The Non-Hardness of Approximating Circuit Size

Eric Allender* Rahul Ilango† Neekon Vafa‡

August 12, 2020

Abstract

The Minimum Circuit Size Problem (MCSP) has been the focus of intense study recently; MCSP is hard for SZK under rather powerful reductions [4], and is provably not hard under “local” reductions computable in $\text{TIME}(n^{0.49})$ [26]. The question of whether MCSP is NP-hard (or indeed, hard even for small subclasses of P) under some of the more familiar notions of reducibility (such as many-one or Turing reductions computable in polynomial time or in AC^0) is closely related to many of the longstanding open questions in complexity theory [7, 8, 19, 20, 21, 23, 26].

All prior hardness results for MCSP hold also for computing somewhat weak approximations to the circuit complexity of a function [3, 4, 10, 19, 24, 31].¹ Some of these results were proved by exploiting a connection to a notion of time-bounded Kolmogorov complexity (KT) and the corresponding decision problem (MKTP). More recently, a new approach for proving improved hardness results for MKTP was developed [5, 7], but this approach establishes only hardness of extremely good approximations of the form $1 + o(1)$, and these improved hardness results are not yet known to hold for MCSP. In particular, it is known that MKTP is hard for the complexity class DET under nonuniform $\leq_m^{\text{AC}^0}$ reductions, implying MKTP is not in $\text{AC}^0[p]$ for any prime p [7]. It was still open if similar circuit lower bounds hold for MCSP. (But see [14, 22].) One possible avenue for proving a similar hardness result for MCSP would be to improve the hardness of approximation for MKTP beyond $1 + o(1)$ to $\omega(1)$, as KT-complexity and circuit size

¹Subsequent to our work, a new hardness result has been announced [22] that relies on more exact size computations.

are polynomially-related. In this paper, we show that this approach cannot succeed.

More specifically, we prove that PARITY does not reduce to the problem of computing superlinear approximations to KT-complexity or circuit size via AC^0 -Turing reductions that make $O(1)$ queries. This is significant, since approximating any set in $P/poly$ AC^0 -reduces to just *one* query of a much worse approximation of circuit size or KT-complexity [28]. For weaker approximations, we also prove non-hardness under more powerful reductions. Our non-hardness results are unconditional, in contrast to conditional results presented in [7] (for more powerful reductions, but for much worse approximations). This highlights obstacles that would have to be overcome by any proof that MKTP or MCSP is hard for NP under AC^0 reductions. It may also be a step toward confirming a conjecture of Murray and Williams, that MCSP is not NP-complete under logtime-uniform $\leq_m^{AC^0}$ reductions.

1 Introduction

The Minimum Circuit Size Problem (MCSP) is the problem of determining whether a (given) Boolean function f (represented as a bitstring of length 2^k for some k) has a circuit of size at most a (given) threshold θ . Although the complexity of MCSP has been studied for more than half a century (see [32, 24] for more on the history of the problem), recent interest in MCSP traces back to the work of Kabanets and Cai [24], who connected the problem to questions involving the natural proofs framework of Razborov and Rudich [30].

Since then, there has been a flurry of research on MCSP [3, 4, 5, 6, 7, 8, 18, 19, 20, 21, 23, 26, 28], but still the exact complexity of MCSP remains unknown. MCSP is in NP, but it remains an important open question whether MCSP is NP-complete.

MCSP is likely not in P. There is good evidence for believing $MCSP \notin P$. If MCSP is in P, then there are no cryptographically-secure one-way functions [24]. Furthermore, [4] shows MCSP is hard for SZK under BPP-Turing reductions, so if $MCSP \in P$ then $SZK \subseteq BPP$, which seems unlikely.

Showing MCSP is NP-hard would be difficult. Murray and Williams [26] have shown that if MCSP is NP-hard under polynomial-time many-one reductions, then $EXP \neq ZPP$, which is a likely separation but one that escapes current techniques. Results from [4, 21, 26] also give various likely (but difficult to show) consequences for MCSP being hard under more restrictive

forms of reduction. We note that it has been suggested that MCSP might well be complete for NP [23]. In this regard, it may also be relevant to note that MCSP^{QBF} is complete for PSPACE under ZPP-Turing reductions [3].

The hardness of both MCSP and approximating MCSP have important consequences for complexity theory. We have already mentioned that if MCSP is NP-hard under polynomial-time reductions, then $\text{EXP} \neq \text{ZPP}$ [26]. In a recent development, Hirahara [18] shows that if a certain approximation to MCSP is NP-hard, then $\text{NP} \not\subseteq \text{BPP}$ implies that NP is difficult to compute even on average. In another recent development, several papers ([29], [27], [25]) study a “hardness magnification” phenomena, whereby seemingly meager $n \cdot \log^{\omega(1)} n$ circuit lower bounds on certain parameterizations of MCSP imply much stronger results such as $\text{NP} \not\subseteq \text{P/poly}$.²

MCSP is not hard for NP in limited settings. Murray and Williams [26] show MCSP is not NP-hard under a certain type of “local” reductions computable in $\text{TIME}(n^{0.49})$. This is significant, since many well-known NP-complete problems are complete under local reductions computable in even logarithmic time. (A list of such problems is given in [26].) Also, under cryptographic assumptions, very weak approximations to MCSP are not NP-hard, even under P/poly reductions [7].

Many hardness results for MCSP also hold for approximate versions of MCSP. In various settings, the power of MCSP to distinguish between functions with circuits of size θ and those requiring size $\theta + 1$ is not needed. Rather, in [3, 10, 4, 31, 28, 23], the reduction succeeds assuming only that reliable answers are given to queries on instances of the form (T, θ) , where either the truth table T requires circuits of size $\geq \theta = |T|$.⁹ or T can be computed by circuits of size $\leq |T|$.⁰¹

This is an appropriate time to call attention to one such reduction to approximations to MCSP. Corollary 66 of [28] shows that, for every small $\delta > 0$, for every solution S to $\text{MCSP}[n^\delta, n^{.5}]$ ³, for every set $A \in \text{P/poly}$, there is a $c > 1$ and a set A' that differs from A on at most $(1/2 - 1/n^c)2^n$ of the strings of each length n , such that $A' \leq_{\text{tt}}^{\text{AC}^0} S$ via a reduction⁴ that makes only *one query*. (That is, $A' \leq_{1\text{-tt}}^{\text{AC}^0} S$.) Stated another way, any set in P/poly

²The hardness magnification result we have stated here is from [25].

³This promise problem is defined formally in Section 2.1.

⁴Although Corollary 6 of [28] does not mention the number of queries, inspection of the proof shows that only one query is performed.

can be “approximated” with just one query to a weak approximation of MCSP. (Changing the solution S will yield a different set A' .)

There is no known many-one hardness result for MCSP, but one is known for a related problem. MKTP, the minimum time-bounded Kolmogorov complexity problem, is loosely the “program version” of MCSP. It is known [7] that MKTP is hard for DET under (non-uniform) NC^0 many-one reductions; it is conjectured that the same is true for MCSP. Time-bounded Kolmogorov complexity is polynomially-related to circuit complexity [3], so one natural way to extend the hardness result of [7] from MKTP to MCSP would be to stretch the very small gap given in the reduction of DET to MKTP.

1.1 Our Contributions, and Related Prior Work

We address the following questions based on prior work:

1. Can the non-hardness result of Murray and Williams [26] be extended to more powerful reductions? Both [26] and [8] conjecture that MCSP is not NP-complete under uniform AC^0 reductions.
2. Can the aforementioned conditional theorem of [7], establishing the non-NP-hardness of very weak approximations to MCSP under cryptographic assumptions, be improved, to show non-NP-hardness of MCSP for stronger approximations?
3. The worst-case to average case reduction given by [18] is conditional on the NP-hardness of a certain approximation to MCSP. Can we say anything about the NP-hardness of this problem in, say, the context of limited reductions?
4. Finally, can the result of [7], showing that MKTP is hard for DET under $\leq_m^{AC^0}$ reductions, be extended, to hold for MCSP as well, by increasing the gap?

Our results give the following replies to these questions:

1. For superlinear approximations to MCSP, one can, in fact, give much stronger non-hardness results than [26], showing non-hardness even under non-uniform AC^0 many-one reductions and even limited types of AC^0 Turing reductions. To our knowledge, this is the first known non-hardness result for any variant of MCSP under non-uniform AC^0

reductions. While AC^0 reductions are provably less powerful than polynomial time reductions, most natural examples of NP-complete problems are easily seen to be complete under AC^0 (and even NC^0 !) reductions [11].

2. [7] shows that, if cryptographically-secure one-way functions exist, then $\epsilon(n)$ -GapMCSP is not hard for NP under P/poly-Turing reductions⁵ for some $\epsilon(n) = n^{o(1)}$. Our result gives a trade-off, where we reduce the gap dramatically but also weaken the type of reduction. In particular, our results imply that if one-way functions exist, then $\epsilon(n)$ -GapMCSP is NP-intermediate under $\leq_m^{AC^0}$ and $\leq_{k-tt}^{AC^0}$ reductions, where $\epsilon(n) = o(n)$.
3. We show that the approximation to MCSP considered by [18] is actually *not* NP-hard under AC^0 reductions.
4. Our work rules out one natural way to extend the MKTP hardness results to MCSP. One might have hoped that the reduction given by [7] could be extended to a larger gap and hence apply to MCSP (since MKTP and MCSP are polynomially related [3]). However, we show that this is impossible.

Our main theorem is an impossibility result in the setting of $\epsilon(\theta)$ -GapMCSP, which is the promise version of MCSP with a multiplicative $\epsilon(\theta)$ gap where θ is the threshold.

Theorem 1. $PARITY \not\leq_m^{AC^0} \epsilon(\theta)$ -GapMCSP where $\epsilon(\theta) = o(\theta)$.

We note that this is not the first work to describe non-hardness of approximation under AC^0 reductions. Arora [12] is credited by [1], with showing that no AC^0 reduction f can have the property that $x \in PARITY$ implies $f(x)$ has a very large clique, and $x \notin PARITY$ implies $f(x)$ has only very small cliques. (In Section 3, we present a similar result for Max-3-SAT, so that the reader can compare the techniques.) Our work differs from that of [12] in several respects. Arora shows that AC^0 reductions cannot prove very *strong* hardness of approximations for a problem where strong inapproximability results are already known. We show that AC^0 reductions cannot establish even very *weak* inapproximability results for MCSP. Also, our techniques allow us to move beyond $\leq_m^{AC^0}$ reductions, to consider AC^0 -Turing reducibility.

⁵The problem ϵ -GapMCSP is defined somewhat differently in [7] than here. See Section 2. Thus the form of $\epsilon(n)$ looks different here than in [7].

All of the theorems that we state in terms of MCSP hold also for MKTP, with identical proofs. For the sake of readability, we present the theorems and proofs only in terms of MCSP.

2 Preliminaries

We use \setminus to denote set difference. For a natural number n , we let $[n]$ denote the set $\{1, \dots, n\}$.

2.1 Defining MCSP

For any binary string T of length 2^k , we define $CC(T)$ to be the size of the smallest circuit (using only NOT gates and AND and OR gates of fan-in 2) that computes the function given by truth table T written in lexicographic order, where, for concreteness, circuit size is defined to be the number of AND and OR gates, although our arguments work for other reasonable notions of circuit size.

Throughout the paper, we use various approximate notions of the minimum circuit size problem, given as follows:

Definition 2 (Gap MCSP). *For any function $\epsilon : \mathbb{N} \rightarrow \mathbb{N}$, we define $\epsilon(n)$ -GapMCSP to be the promise problem (Y, N) where*

$$Y := \{(T, \theta) \mid CC(T) \leq \epsilon(\theta)\}, \text{ and} \\ N := \{(T, \theta) \mid CC(T) > \theta\},$$

where θ is written in binary.

Note that this definition differs in minor ways from the way that ϵ -GapMCSP was defined in [7]. The definition presented here allows for finer distinctions than the definition that was used in [7].

Our results for non-hardness under $\leq_T^{AC^0}$ reductions are best stated in terms of a restricted version of ϵ -GapMCSP, where the thresholds are fixed, for inputs of a given size: This variant of MCSP has been studied previously in [26, 19]; an analogous problem defined in terms of KT-complexity is denoted R_{KT} in [3].

Definition 3 (Parameterized Gap MCSP). *For any functions $\ell, g : \mathbb{N} \rightarrow \mathbb{N}$ such that $\ell(n) \leq g(n)$, We define the language $MCSP[\ell, g]$ to be the promise problem (Y, N) where*

$$Y := \{T \mid CC(T) \leq \ell(|T|)\}, \text{ and} \\ N := \{T \mid CC(T) > g(|T|)\}.$$

2.2 Complexity classes and Reductions

We assume the reader is familiar with basic complexity classes such as P and NP . As we work extensively with non-uniform NC^0 and AC^0 , we refer to the text by Vollmer [33] for background on these circuit classes. Throughout this paper, unless otherwise explicitly mentioned, we refer to the non-uniform versions of these circuit classes.

Let \mathcal{C} be a class of circuits. For any languages A and B , we write $A \leq_m^{\mathcal{C}} B$ if there is a function f computed by a circuit family $\{C_n\} \in \mathcal{C}$ such that $f(x) \in B \iff x \in A$. We write $A \leq_T^{\mathcal{C}} B$ if there is a circuit family in \mathcal{C} computing A with B -oracle gates. In particular, since we are primarily concerned with $\mathcal{C} = AC^0$, we denote this as $A \leq_T^{AC^0} B$. We write $A \leq_{tt}^{AC^0} B$ if there is an AC^0 circuit family computing A with B -oracle gates, where there is no directed path from any oracle gate to another, i.e. if the reduction is non-adaptive. If, furthermore, the non-adaptive reduction has the property that each of the oracle circuits contains at most k oracle gates, then we write $A \leq_{k-tt}^{AC^0} B$.

Let $Y \subseteq \{0, 1\}^*$ and $N \subseteq \{0, 1\}^*$ be disjoint. Then $\Pi = (Y, N)$ is a *promise problem*. A language L is a *solution* to a promise problem $\Pi = (Y, N)$ if $Y \subseteq L$ and $N \cap L = \emptyset$. For two promise problems Π_1 and Π_2 , some type of reducibility r (many-one, truth table, or Turing), and a circuit class \mathcal{C} , we say $\Pi_1 \leq_r^{\mathcal{C}} \Pi_2$ if there is a *single* family of oracle circuits $\{C_n\}$ in \mathcal{C} such that for every solution S_2 of Π_2 , there is a solution S_1 of Π_1 such that C_n computes an r -reduction from S_1 to S_2 .

2.3 Boolean Strings and Functions

For an $x \in \{0, 1\}^n$ and a set of indices $B \subseteq [n]$, we let x^B denote the Boolean string obtained by flipping the i th bit of x for each $i \in B$.

A *partial string* (or *restriction*) is an element of $\{0, 1, ?\}^*$. Define the *size* of a partial string p to be the number of bits in which it is $\{0, 1\}$ -valued. We say a partial string $p \in \{0, 1, ?\}^n$ *agrees* with a binary string $x \in \{0, 1\}^n$ if they agree on all $\{0, 1\}$ -valued bits. If $x \in \{0, 1\}^n$ is a binary string and $B \subseteq [n]$, then $x|_B$ denotes the partial string given by replacing the j th bit of x with $?$ for each $j \in [n] \setminus B$. We say a partial string p_1 *extends* a partial string p_2 if p_1 is equal to p_2 on all bits where p_2 is $\{0, 1\}$ -valued.

A *partial Boolean function* on n variables is a function $f : I \rightarrow \{0, 1\}$ where $I \subseteq \{0, 1\}^n$. For a promise problem $\Pi = (Y, N)$ and $n \in \mathbb{N}$, we let $\Pi|_n$ be the partial Boolean function that decides membership in Y on instances of length n which satisfy the promise. (In particular, $\Pi|_n : I :=$

$(Y \cup N) \cap \{0, 1\}^n \rightarrow \{0, 1\}$.)

We will make use of two well-studied complexity measures on Boolean functions: block sensitivity and certificate complexity. We refer the reader to a detailed survey by Hatami, Kulkarni, and Pankratov [17] for background on these notions. For completeness, we provide the definitions of the two measures that we need. In our context, we will use these measures on partial Boolean functions. Let $I \subseteq \{0, 1\}^n$ and let $f : I \rightarrow \{0, 1\}$ be a partial Boolean function. For an input $x \in I$, define the *block sensitivity of f at x* , denoted $bs(f, x)$, to be the maximum number of non-empty, disjoint sets B_1, \dots, B_k such that $x^{B_i} \in I$ and $f(x) \neq f(x^{B_i})$ for all i . (Here, by “ $f(y) \neq f(z)$ ” we require that f is defined at both y and z .) Define the *0-block sensitivity of f* to be $bs_0(f) := \max_{x: f(x)=0} bs(f, x)$. For an input $x \in I$, define the *certificate complexity of f at x* , denoted $c(f, x)$, to be the size of the smallest set $B \subseteq [n]$ such that $f(y) = f(x)$ for all $y \in I$ that agree with $x|_B$. Define the *0-certificate complexity of f* to be $c_0(f) := \max_{x: f(x)=0} c(f, x)$.

3 Prior Work

In this section, we present a result that is similar in spirit to a result reported by Arora in an unpublished manuscript [12]. There, it was shown that there is no AC^0 -computable function f with the property that $x \in \text{PARITY}$ implies $f(x)$ has a very large clique, and $x \notin \text{PARITY}$ implies $f(x)$ has only very small cliques. Here, in order to illustrate the techniques that were employed in [12], we observe that no AC^0 reduction can establish the known inapproximability of Max-3-SAT [16].

Our results, like those of [12], rely on the following lemma, which says that it is possible to apply a restriction to a family of AC^0 circuits and thereby obtain a family of NC^0 circuits. This lemma is implicit in the earliest lower bound work on AC^0 [2, 13], and was stated and proved in this form in [1].

Lemma 4 (Lemma 7 in [1]). *Let C_n be a family of n -input (multi-output) AC^0 circuits. Then there exists an $a > 0$ such that for all $n \in \mathbb{N}$ there exists a restriction of C_n to $\Omega(n^{1/a})$ input variables that transforms C_n into a (multi-output) NC^0 circuit.*

Here, when we say that a restriction “transforms” a circuit into a NC^0 circuit, we mean the process whereby any OR gate that has a constant 1 feeding into it (say, from the restriction) can be replaced by a constant 1, and any AND gate that has a 0 feeding into it can be replaced by a constant 0, and this process can be repeated until no more simplification is possible.

Proposition 5. *Let $0 < \epsilon < 1$. No AC^0 reduction f can have the property that $x \in \text{PARITY}$ implies $f(x) \in 3\text{-SAT}$, and $x \notin \text{PARITY}$ implies $f(x)$ has at most an ϵ fraction of the clauses satisfied.*

Proof. By appealing to Lemma 4, we may assume that the function f is an NC^0 reduction. (A more careful argument, explaining how this assumption is justified, is provided in the proof of Theorem 1.) Let d be the constant, such that each output bit of $f(x)$ depends on at most d bits of x , and let $x \in \text{PARITY}$ have length n . Let $f(x)$ consist of m clauses, each encoded using $c \log m$ bits for some constant c (which we can assume since the number of clauses is polynomially-related to the number of variables). Then since $|f(x)| = cm \log m$, and each output bit depends on at most d input bits, there is some $i \leq n$ such that the i -th bit of x affects at most $(dcm \log m)/n$ output bits. Flipping the i -th bit of x , to obtain a new string $x' \notin \text{PARITY}$ can affect at most $(dcm \log m)/n$ clauses. Since $f(x) \in 3\text{-SAT}$, there is an assignment that satisfies at least $m - (dcm \log m)/n$ clauses of $f(x')$. The theorem is proved, by observing that $m - (dcm \log m)/n > \epsilon m$ for all large m . \square

This discussion of prior work is also the appropriate place to mention that a preliminary version of this article appeared in a conference proceedings [9]. Several proofs were omitted from the conference publication, due to space limitations, and they are presented in full here.

4 Non-Hardness Under NC^0 Reductions

In this section, we prove our main lemmas, showing that problems that are NC^0 -reducible to $\epsilon\text{-GapMCSP}$ have bounded 0-block sensitivity and also have sublinear 0-certificate complexity. Whenever we will have occasion to use these lemmas, it will be in situations when we are able to assume that the NC^0 reduction is computing a function f satisfying the condition that there is a bound $\gamma(n) > 0$ such that, for all n , there is a $\theta \geq \gamma(n)$ such that, for all x of length n , $f(x)$ is of the form $(T(x), \theta)$. (In particular, the threshold θ is the same for all inputs of length n .) We will call such an NC^0 reduction a γ -honest reduction.

Lemma 6. *Let $\epsilon(\theta) = o(\theta)$, and let $\Pi = (Y, N)$ be a promise problem, where $\Pi \leq_m^{\text{NC}^0} \epsilon\text{-GapMCSP}$ via a γ -honest reduction f computed by an NC^0 circuit family C_n of depth $\leq d$, where $\gamma(n) \geq \log \log n$. Then there is an n_0 (that depends only on ϵ and d) such that for all $n \geq n_0$, if $N|_n \neq \emptyset$, then $bs_0(\Pi|_n) < s$, where s is a constant that depends only on d .*

Proof. Let $s = 2^{d+1} + 1$. Since $\epsilon(n) = o(n)$, we can pick a constant $r_0 > 4s$ such that $\epsilon(r) < r/(2s)$ for all $r \geq r_0$.

Pick $n_0 \geq 2^{2^{r_0}}$, and let $n \geq n_0$.

For the sake of contradiction, suppose $bs_0(\Pi|_n) \geq s$, and let $x \in N \cap \{0, 1\}^n$ be a 0-valued instance with $bs(\Pi|_n, x) \geq s$. Then we can find disjoint sets $B_1, \dots, B_s \subseteq [n]$ such that $\Pi|_n(x^{B_j}) = 1$ for all $j \in [s]$. (That is, each x^{B_j} is in Y .)

Let $f(x) = (T, \theta)$, and note that $CC(T) > \theta \geq \gamma(n)$ (since f is γ -honest). Since $x \in N$ and C_n is a reduction to ϵ -GapMCSP, we know that any circuit that computes the function with truth table T has size at least θ . For each $j \in [s]$, let T_j be the truth table produced by C_n on input x^{B_j} . Since $x^{B_j} \in Y$, we know that each T_j has a circuit D_j computing T_j of size at most $\epsilon(\theta)$. (Here, it is important that the same threshold θ is used for all inputs of length n , by γ -honesty.)

We aim to build a “small” circuit computing T , which would contradict T having high complexity. Our circuit C for computing T works as follows: on input i , output the majority of $D_1(i), \dots, D_s(i)$. The size of C is at most $s \cdot \epsilon(\theta) + 2s$ (each D_j has size at most $\epsilon(\theta)$, and computing the majority of s bits can be done with a circuit of size $2s$).

Now, we argue that this circuit correctly computes the i th bit of T for all i . Let i be arbitrary. Recall the i th bit of T is defined to be the i th output of $C_n(x)$. Since C_n is a depth d circuit of fan-in 2, the i th output of C_n depends on at most 2^d input wires $W \subseteq [m]$. Hence, on any input y such that $y|_W = x|_W$, we have that the i th output of $C_n(y)$ equals the i th output of $C_n(x)$. In particular, if B is disjoint from W , then the i th output of $C_n(x^B)$ equals the i th output of $C_n(x)$. Since B_1, \dots, B_s are disjoint and $|W| \leq 2^d$, it follows that at most 2^d of the sets B_1, \dots, B_s have a non-empty intersection with W . Hence, since $s = 2^{d+1} + 1$, the majority of the sets B_1, \dots, B_s are disjoint with W , so the majority of the circuits D_1, \dots, D_s when run on input i output the i th output of $C_n(x)$.

We thus have that $CC(T) \leq s \cdot \epsilon(\theta) + 2s$. But $\theta > \gamma(n) \geq \log \log n$ (since the reduction f is γ -honest). By the choice of n_0 we have $\epsilon(\theta) < \theta/2s$ (since $\theta > \log \log n \geq r_0$). Thus $CC(T) \leq s \cdot \theta/2s + 2s = \theta/2 + 2s < \theta$ (since $\theta > \log \log n > 4s$). This contradicts $CC(T) > \theta$. \square

The reader who is interested primarily in Theorem 1 (which shows that Gap MCSP is not NP-hard under nonuniform AC^0 m-reductions) can skip ahead to Section 5. The rest of this section develops tools that are used in our results that deal with more powerful notions of reducibility.

Lemma 7. *Let $\epsilon(\theta) = o(\theta)$, and let $\Pi = (Y, N)$ be a promise problem, where $\Pi \leq_m^{\text{NC}^0} \epsilon\text{-GapMCSP}$ via a γ -honest reduction f computed by an NC^0 circuit family C_n of depth $\leq d$, where $\gamma(n) \geq \log \log n$. Let $k \geq 1$. Then there is an n_0 (that depends only on ϵ, k and d) such that for all $n \geq n_0$, if $N|_n \neq \emptyset$, then $c_0(\Pi|_n) \leq n/k$.*

Proof. Let $p = 2^d$, let $p' = \binom{2pk+1}{p}$, and let K be a constant that is specified later (and which depends only on k and d). Since $\epsilon(\theta) = o(\theta)$, we can pick a constant s_0 such that $\binom{p'}{2}\epsilon(s) + K < s$ for all $s \geq s_0$.

Pick $n_0 \geq 2^{2^{s_0}}$, and let $n \geq n_0$.

For contradiction, suppose $c_0(\Pi|_n) > n/k$. Let $x \in N \cap \{0, 1\}^n$ be a 0-valued instance with $c_0(\Pi|_n, x) > n/k$. Then, for all $S \subseteq [n]$ with $|S| \leq n/k$, there is an x_S such that x_S agrees with $x|_S$ and such that $\Pi|_n(x_S) = 1$. (That is, $x_S \in Y$.)

Let (T, θ) be the truth table produced by C_n on input x . Since $x \in N$ and C_n is a reduction, we know that any circuit computing T has size at least θ .

For each $S \subseteq [n]$ with size at most n/k , let T_S be the truth table produced by C_n on input x_S . Since $x_S \in Y$, we know that T_S has a circuit D_S of size at most $\epsilon(\theta)$.

We aim to build a “small” circuit computing T , which would contradict that T has high complexity. Recall that $p = 2^d$, and that $p' = \binom{2pk+1}{p}$.

Claim 1. *There exist sets $S_1, \dots, S_{p'} \subseteq [n]$ such that*

- $|S_i| \leq \frac{n}{2k}$ for all i , and
- for any set $P \subseteq [n]$ with $|P| \leq p$, we have that $P \subseteq S_i$ for some i .

Proof. (Proof of Claim) Pick sets $V_1, \dots, V_{2pk+1} \subseteq [n]$ of size at most $\frac{n}{2pk}$ whose union is $[n]$. Let $\mathcal{V} = \{V_1, \dots, V_{2pk+1}\}$. Now let each of $S_1, \dots, S_{\binom{2pk+1}{p}}$ be the union of some p sets chosen from \mathcal{V} . Each S_i has size at most $p \frac{n}{2pk} = \frac{n}{2k}$. Let $P \subseteq [n]$ be an arbitrary set of size p . Since $\bigcup_{V \in \mathcal{V}} V = [n]$, every element e of P lies within some $V \in \mathcal{V}$. Then P is contained in the union of some p sets from \mathcal{V} , so $P \subseteq S_i$ for some i . \square

For each $i \neq j \in [p']$, let $S_{i,j} = S_{j,i} = S_i \cup S_j$. Note that $|S_{i,j}| \leq n/k$.

Our circuit C for computing T works as follows. On input r , for each $i \in [p']$, see if $D_{S_{i,1}}(r) = \dots = D_{S_{i,p'}}(r)$. If so, then output $D_{S_{i,1}}(r)$. The size of this circuit is at most $\binom{p'}{2}\epsilon(\theta) + K$ (for some fixed constant K) since each of the $\binom{p'}{2}$ $D_{S_{i,j}}$ circuits has size at most $\epsilon(\theta)$ and the other “unanimity”

condition is a Boolean function on $\binom{p'}{2}$ variables (of in fact linear size) and so can be computed with circuit of some size $K = O(p')^2$ (that depends only on k and d).

Now, we argue that C on input r correctly computes the r th bit of T . Let $r \in [m]$ be arbitrary. For convenience, given any input $y \in \{0, 1\}^n$ let $C_n^r(y)$ denote the r th output of $C_n(x)$. Recall the r th bit of T is defined to be $C_n^r(x)$. We must show two things. First, that there exists an i such that $D_{S_{i,1}}(r) = \dots = D_{S_{i,p'}}(r)$ and second, that if for some i we have that $D_{S_{i,1}}(r) = \dots = D_{S_{i,p'}}(r)$, then $D_{S_{i,1}}(r) = C_n^r(x)$.

Since C_n has depth d , the r th output of C_n can depend on at most 2^d input wires $W \subseteq [m]$. Hence, on any input y such that $y|_W = x|_W$, we have that $C_n^r(y) = C_n^r(x)$. Since $p = 2^d$, by the claim, there exists some S_{i^*} such that $W \subseteq S_{i^*}$. Therefore, for all j we have that $x_{S_{i^*,j}}|_W = x|_W$, so

$$D_{S_{i^*,j}}(r) \stackrel{\text{def}}{=} C_n^r(x_{S_{i^*,j}}) = C_n^r(x).$$

This implies both things we must show. First, we know that $D_{S_{i^*,1}}(r) = \dots = D_{S_{i^*,p'}}(r)$ since they each equal $C_n^r(x)$. Second, if for some i , we have that $D_{S_{i,1}}(r) = \dots = D_{S_{i,p'}}(r)$, then we also have that $D_{S_{i,1}}(r) = D_{S_{i,i^*}}(r) = C_n^r(x)$.

Thus we have that T can be computed by a circuit of size at most $\binom{p'}{2}\epsilon(\theta) + K$, which is less than θ , since $\theta \geq \log \log n \geq s_0$. This contradicts that $\text{CC}(T) > \theta$. \square

Next, we note that one can improve the bounds given by Lemma 7 assuming a larger gap.

Lemma 8. *Let $\epsilon(\theta) < \theta^\alpha$, and let $\Pi = (Y, N)$ be a promise problem, where $\Pi \leq_m^{\text{NC}^0} \epsilon\text{-GapMCSP}$ via a γ -honest reduction f computed by an NC^0 circuit family C_n of depth $\leq d$, where $\gamma(n) \geq n^\beta$. Then for all δ such that $\delta_0 = \beta(1 - \alpha)/2^{d+1} > \delta > 0$ there is an n_0 such that for all $n \geq n_0$, if $N|_n \neq \emptyset$, then $c_0(\Pi|_n) \leq n^{1-\delta}$.*

Proof. Let $p = 2^d$. Suppose for contradiction that for some $\delta > 0$ with $\delta < \delta_0 = \beta(1 - \alpha)/2p$ we have $c_0(\Pi|_n) > n^{1-\delta}$ infinitely often. We can follow the same argument (and notation) as above, except we have to be more careful since $n/c_0(\Pi|_n)$ is no longer a constant, and hence $p' = \binom{2pn/c_0(\Pi|_n)+1}{p} \leq \binom{2pn^\delta+1}{p} = O(n^{p\delta})$ is no longer constant. Since the unanimity condition can be implemented by a circuit of size linear in $\binom{p'}{2}$, we can construct a circuit computing truth table T of size

$$\epsilon(\theta) \cdot c_1 p'^2 = \epsilon(\theta) \cdot c_1 \binom{2pn^\delta + 1}{p}^2 \leq c_2 \epsilon(\theta) n^{2p\delta}$$

infinitely often for some positive constants c_1, c_2 . By γ -honesty, we have $\theta \geq \gamma(n) \geq n^\beta$. This implies that we can construct a circuit computing T of size

$$c_2\epsilon(\theta)n^{2p\delta} \leq c_2\epsilon(\theta)(\theta^{1/\beta})^{2p\delta} < c_2\theta^\alpha\theta^{2p\delta/\beta} < \theta$$

infinitely often. This is a contradiction since T is a truth table with circuit complexity $\geq \theta$. \square

Next, we present a variant of Lemma 8, but restricted to the parameterized version of **MCSP**. This variant is useful in extending our non-hardness results to $\leq_T^{\text{AC}^0}$ reductions that make $n^{o(1)}$ queries.

Lemma 9. *Let $\Pi = (Y, N)$ be a promise problem. If $\Pi \leq_m^{\text{NC}^0} \text{MCSP}[\ell, g]$ with $\ell(m) = o(g(m)/m^\delta)$ for some $\delta > 0$, then $c_0(\Pi|_n) \leq n^\epsilon$ for some $\epsilon < 1$ for all but finitely many n where $N|_n \neq \emptyset$, where ϵ depends only on the depth of the NC^0 circuit family and δ .*

Proof. Suppose for contradiction that for all $\epsilon < 1$ we have $c_0(\Pi|_n) > n^\epsilon$ infinitely often. Once again, we follow the same argument (and notation) as above. We can construct a circuit computing truth table T of size

$$\ell(m) \cdot c_1 p'^2 \leq \ell(m) \cdot c_1 \binom{2pn/c_0(\Pi|_n) + 1}{p}^2 \leq \ell(m) c_1 \binom{2pn^{1-\epsilon} + 1}{p}^2 \leq c_2 \ell(m) n^{2p(1-\epsilon)},$$

infinitely often for some positive constants c_1, c_2 . (Here, m denotes the length of the truth table T .) Note that since $c_0(\Pi|_n) > n^\epsilon$, we know $\Pi|_n$ depends on $\geq n^\epsilon$ input bits. Since the circuit has depth at most d and gates of fan-in 2, we must have $m \geq n^\epsilon/2^d$. This implies that we can construct a circuit computing T of size

$$c_2 \ell(m) (n^\epsilon)^{\frac{2p(1-\epsilon)}{\epsilon}} \leq c_3 \ell(m) m^{\frac{2p(1-\epsilon)}{\epsilon}},$$

infinitely often for some positive constant c_3 . Setting $\epsilon = \frac{2p}{2p+\delta}$, we have that T can be computed by a circuit of size $\leq c_3 \ell(m) \cdot m^\delta$ infinitely often, which is a contradiction since T is a truth table with circuit complexity $\geq g(m) = \omega(\ell(m) \cdot m^\delta)$. \square

5 Non-Hardness Under Many-One AC^0 Reductions

In this section, we use the tools of the preceding section to show that the problem of approximating circuit size is not hard for any class containing **PARITY** under $\leq_m^{\text{AC}^0}$ reductions. We recall Theorem 1:

Theorem 1. $\text{PARITY} \not\leq_m^{\text{AC}^0} \epsilon\text{-GapMCSP}$ where $\epsilon(n) = o(n)$.

Proof. Suppose not. Then there is a family of AC^0 circuits C_n that many-one reduces PARITY to $\epsilon\text{-GapMCSP}$. By Lemma 4, there is an a such that we can transform each C_n into an NC^0 circuit D_m on $m = \Omega(n^{1/a})$ variables, computing a reduction f from either PARITY or $\neg\text{PARITY}$ (depending on the parity of the restriction) to $\epsilon\text{-GapMCSP}$. For each input x of length n , $f(x)$ is of the form $(T(x), \theta(x))$. Since there are only $O(\log n)$ output gates in the $\theta(x)$ field, and each output gate depends on only $O(1)$ input variables, all of the output gates for $\theta(x)$ can be fixed by setting only $O(\log n)$ input variables. Furthermore, we claim that there is some setting of these $O(\log n)$ input variables, such that the resulting value of θ is greater than $\log n / \log \log n$. If this were not the case, then the $\leq_m^{\text{AC}^0}$ reduction of PARITY (or $\neg\text{PARITY}$) on $m = \Omega(n^{1/a})$ variables to $\epsilon\text{-GapMCSP}$ has the property that $\theta(x)$ is always less than $\log n / \log \log n$. But, as in the proof of Theorem 1.3 of [26], instances of MCSP where θ is $O(\log n / \log \log n)$ can be solved with a DNF circuit of polynomial size. Thus this would give rise to AC^0 circuits for PARITY , contradicting the well-known circuit lower bounds of [2, 13].

Summarizing up to this point: The circuits D_m with $O(\log n)$ additional variables set (fixing the value of θ) yields a family on $m' = m - O(\log n) = \Omega(n^{1/(a+1)})$ variables, where each circuit $D_{m'}$ reduces either PARITY or $\neg\text{PARITY}$ to $\epsilon\text{-GapMCSP}$, where furthermore this reduction satisfies the hypotheses of Lemmas 6 and 7.

But then the conclusions of Lemmas 6 and 7 contradict the fact that both PARITY and $\neg\text{PARITY}$ on m' variables have 0-certificate complexity and 0-block-sensitivity m' . \square

6 Non-Hardness Under Limited Turing AC^0 Reductions

With some work, we can extend our non-hardness results beyond many-one reductions to some limited Turing reductions.

In our proofs that deal with AC^0 -Turing reductions, we will need to replace some oracle gates with “equivalent” hardware — where this hardware will provide answers that are consistent with *some* solution to the promise problem $\epsilon\text{-GapMCSP}$, but might not be consistent with the particular solution that is provided as an oracle. In order to ensure that this doesn’t cause any problems, we introduce the notion of a “sturdy” AC^0 -Turing reduction:

Definition 10. Let $\Pi_1 = (Y_1, N_1)$ and $\Pi_2 = (Y_2, N_2)$ be promise problems. A family $\{C_n\}$ of AC^0 -oracle circuits is a sturdy $\leq_{\text{T}}^{\text{AC}^0}$ reduction from Π_1 to Π_2 if, for every pair of solutions S, S' to Π_2 , every oracle gate G in C_n , and every $x \in Y_1 \cup N_1$, there is a solution S'' such that $C_n^S(x) = C_n^{S''}(x) = C_n^S[G \rightarrow S'](x)$, where the notation $C_n^S[G \rightarrow S']$ refers to the circuit C_n with oracle S , but where the oracle gate G answers queries according to the solution S' instead of S .

Lemma 11. Let Π be any promise problem. If $\Pi \leq_{\text{tt}}^{\text{AC}^0} \epsilon(n)\text{-GapMCSP}$ via a reduction of depth d , then $\Pi \leq_{\text{tt}}^{\text{AC}^0} \epsilon(n)\text{-GapMCSP}$ via a sturdy reduction of depth $5d$ with the same number of oracle gates. If $\Pi \leq_{\text{T}}^{\text{AC}^0} \epsilon(n)\text{-GapMCSP}$ via a reduction of depth d , then $\Pi \leq_{\text{T}}^{\text{AC}^0} \epsilon(n)\text{-GapMCSP}$ via a sturdy reduction of depth $5d$ with the same number of oracle gates.

Proof. Briefly: We modify C_n , so that each oracle query is checked against queries that were asked “earlier” in the computation, and the computation uses only the oracle answer from the first time a query was asked. Since each query is given an answer that is consistent with *some* solution, the new circuit gives the same answers as a new solution (which we denote as S''). Since C_n is a reduction, we get the same answer when using S or S'' .

In more detail: Label the oracle gates G_1, \dots, G_k of C_n in topological order so that there is no directed path from G_i to G_j for all $i > j$ (and for a truth-table reduction, any ordering suffices). Let q_i denote the query asked by G_i . Let C'_n be the circuit where we replace any wire that leaves G_i by a wire connected to the following subfunction:

$$\begin{aligned} & G_i(x) \wedge \forall j < i (q_i \neq q_j) \\ & \text{or} \\ & \exists j < i (q_i = q_j \wedge \forall k < j (q_k \neq q_j) \wedge G_j(q_j)) \end{aligned}$$

The reader can verify that this additional circuitry can be implemented in depth five, and thus C'_n has depth at most $5d$. Furthermore, this hardware does not add any oracle gates or directed paths between oracle gates, so the number of oracle gates used is unchanged and truth-table reductions remain truth-table reductions.

Now let S and S' be any two solutions to $\epsilon(n)\text{-GapMCSP}$. Consider any input x of length n that satisfies the promise of $\Pi = (Y, N)$. (That is, $x \in Y \cup N$.) Thus $C_n^S(x) = C_n^{S'}(x)$. Now consider the operation of $C'_n(x)$ where some oracle gate G_i answers queries according to S' , rather than S . By construction, the behavior of this computation $C_n^S[G_i \rightarrow S']$ is the same

as that of $C_n^{S''}(x)$, where

$$S''(q(x)) := \begin{cases} S(q(x)) & \text{if } q(x) \neq q_i(x), \text{ or if } q_i(x) = q_j(x) \text{ for some } j < i, \\ S'(q(x)) & \text{otherwise.} \end{cases}$$

S'' is also a solution to ϵ -GapMCSP, since it agrees with either S or S' on each query, and both S and S' agree on all queries that satisfy the promise. Thus $C_n^{S''}[G_i \rightarrow S'](x) = C_n^{S''}(x) = C_n^{S'}(x) = C_n^S(x)$, since C_n is a reduction. Also, $C_n^{S''}(x) = C_n^{S'}(x)$ and $C_n^{S'}(x) = C_n^S(x)$, since each oracle gate of C_n' answers each query the same way that C_n does, if the same oracle is provided to each gate. Thus, we have that $C_n^{S'}(x) = C_n^{S''}(x) = C_n^{S'}[G_i \rightarrow S'](x)$. This establishes that C_n' is computing a sturdy reduction. \square

Theorem 12. *Let $k \geq 1$, and let $\epsilon(n) = o(n)$. Then $\text{PARITY} \not\leq_{k\text{-tt}}^{\text{AC}^0} \epsilon\text{-GapMCSP}$.*

Proof. We show that, for all $k \geq 1$, if $\text{PARITY} \leq_{k\text{-tt}}^{\text{AC}^0} \epsilon\text{-GapMCSP}$, then $\text{PARITY} \leq_{(k-1)\text{-tt}}^{\text{AC}^0} \epsilon\text{-GapMCSP}$. This suffices, since a 0-truth-table reduction is simply an AC^0 circuit computing PARITY , which cannot exist.

Given the oracle circuit family C_n , (where by Lemma 11 we may assume that the $\leq_{k\text{-tt}}^{\text{AC}^0}$ reduction is sturdy), let D_n be the subcircuit consisting of those gates that are on a path from an input variable to any oracle gate. D_n is simply an AC^0 circuit on n variables, and thus by Lemma 4, there is an a such that we can transform each D_n into an NC^0 circuit $E_{m(n)}$ on $m(n) = \Omega(n^{1/a})$ variables. Replacing D_n by $E_{m(n)}$ in C_n yields a $k\text{-tt}$ reduction $F_{m(n)}$ from PARITY or $\neg\text{PARITY}$ on $m(n)$ variables to $\epsilon\text{-GapMCSP}$. (If $F_{m(n)}$ is a reduction from $\neg\text{PARITY}$, then modify $F_{m(n)}$ by negating the output gate, so that each $F_{m(n)}$ is a reduction from PARITY on $m(n)$ variables to $\epsilon\text{-GapMCSP}$.) Note that we can obtain a family of polynomial-size circuits on n variables by starting with $F_{m(n^{2a})}$ (which has more than n input variables) and setting some of the variables to 0. Thus, without any loss of generality, we may assume that our circuit family C_n has the property that the subcircuit D_n consisting of the gates on a path from an input gate to an oracle gate consists of NC^0 circuitry.

For each n , select the first oracle gate G_1 (in some order). Consider the circuit family B_n consisting of all of the gates that are on a path from any input to G_1 . Note that B_n is an NC^0 circuit family computing some function f , where $f(x)$ is of the form $(T(x), \theta(x))$. If it is possible to set some of the input variables of B_n so that the output gates for $\theta(x)$ take on a value $\theta \geq \log n / \log \log n$, do so. Note that this leaves $m = n - O(\log n)$ variables

unset. (If it is not possible to do so, then (as in the proof of Theorem 1), G_1 can be replaced in C_n by a polynomial-sized DNF circuit, thereby yielding a (sturdy) $(k-1)$ -tt reduction, as desired.) Call C'_m and B'_m the circuits that result by restricting the $O(\log n)$ input variables of C_n and B_n , respectively.

We now aim to find a restriction of the inputs and a solution to ϵ -GapMCSP such that the output of G_1 is constant. Define $\Pi = (Y, N)$ to be the promise problem where for all x we put $x \in Y$ if and only if $\text{CC}(T(x)) \leq \epsilon(\theta)$ and $x \in N$ if and only if $\text{CC}(T(x)) > \theta$ where $B'_m(x) = (T(x), \theta)$. Observe that B'_m is a log n -honest NC^0 reduction of Π to ϵ -GapMCSP.

There are two cases, depending on whether $N = \emptyset$ or not. If $N = \emptyset$, then $S' = \{(T, \theta) : \text{CC}(T) \leq \epsilon(\theta)\}$ is a solution to ϵ -GapMCSP such that every query to G_1 is answered affirmatively. By the sturdiness of the reduction, G_1 can be replaced by a constant 1, transforming C'_m into a $(k-1)$ -tt reduction.

If $N \neq \emptyset$, then by Lemma 7, for all large m $c_0(\Pi|_m) \leq m/(k+1)$. That is, there is a way to set some $r \leq m/(k+1)$ input variables, obtaining restriction ρ , and thereby obtain a circuit $B''_{m-r} = B'_m|_\rho$ on $m-r$ variables, such that for any string z of length $m-r$, $\text{CC}(T_{m-r}(z)) > \epsilon(\theta)$ where $B''_{m-r}(z) = (T_{m-r}(z), \theta)$. That is, every query to G_1 is answered negatively in $C'_m|_\rho$, and hence G_1 can be replaced by a constant 0, transforming $C'_m|_\rho$ into a $(k-1)$ -tt reduction from PARITY to ϵ -GapMCSP on $m-r = \Omega(n)$ variables in this case.

In both cases, we obtain a $(k-1)$ -tt reduction from PARITY to ϵ -GapMCSP, as desired. \square

With a larger gap, we can rule out nonadaptive reductions that use $n^{o(1)}$ queries.

Theorem 13. *Let $\epsilon(n) < n^\alpha$ for some $1 > \alpha > 0$. Then for any circuit family $\{C_n\}$ computing an $\leq_{\text{tt}}^{\text{AC}^0}$ reduction of PARITY to ϵ -GapMCSP, there is a $\delta > 0$ such that, for all large n , C_n makes at least n^δ queries.*

Proof. Let $\{C_n\}$ be a circuit family computing an $\leq_{\text{tt}}^{\text{AC}^0}$ reduction of PARITY to ϵ -GapMCSP. By Lemma 11 we may assume that each C_n is sturdy. As in the proof of the preceding theorem, we assume without loss of generality that C_n has the property that the subcircuit D_n consisting of those gates that lie on paths from input gates to oracle gates consists of NC^0 circuitry of depth d . (We will assume without loss of generality that, if the gates in D_n are removed from C_n , the depth of the circuit that remains is also at most d . Otherwise, let d be the maximum of these two constants.)

We will show that, for all large n , C_n contains at least n^δ oracle gates G_1, G_2, \dots, G_t , where δ is chosen to be less than $(1-\alpha)/12d2^{d+1}$. For the

sake of a contradiction, assume that $t < n^\delta$.

Here is a high-level overview of the rest of the proof: As in the proof of the preceding theorem, we construct a sequence of restrictions (one for each oracle gate), so that when the input bits of C_n are set according to the restrictions, each oracle gate either has a very small threshold θ , or else it can be replaced by a constant. In this way, we transform C_n into a circuit on $m \geq n/2$ input bits where each oracle gate G_i has a threshold $\theta_i < n^{1/3d}/\log n$. Replacing each such oracle gate by a DNF of size $2^{O(n^{1/3d})}$ (as in the proof of the preceding theorem) results in an AC^0 circuit of depth at most $d + 1$ computing PARITY, in contradiction to the lower bound of [15]. Details follow.

Our argument proceeds in t stages, where oracle gate G_i is considered in stage i . At the start of stage i we have a partial restriction ρ_{i-1} that has at most $(i-1)n^{1-2\delta}$ bits set. Here is a detailed description of stage i :

Consider the circuit family B_n consisting of all of the gates that are on a path from any input to G_i . Note that B_n is an NC^0 circuit family computing some function f_i , where $f_i(x)$ is of the form $(T_i(x), \theta_i(x))$. If for all x that agree with ρ_{i-1} , $\theta_i(x) < n^{1/(3d)}/\log(n)$, then stage i is done; set $\rho_i = \rho_{i-1}$ and go on to the next stage. Otherwise, there is a way to set an additional $O(\log n)$ additional variables, thereby extending ρ_{i-1} to obtain a new restriction ρ'_i , so that for all x which agree with ρ'_i , $\theta_i(x)$ takes on a constant value $\theta_i \geq n^{1/(3d)}/\log n \geq n^{1/(4d)}$.

We now aim to find a restriction of the inputs and a solution to ϵ -GapMCSP such that the output of G_i is constant. Define $\Pi_i = (Y_i, N_i)$ to be the promise problem where for all x that agree with ρ'_i we put $x \in Y_i$ if and only if $CC(T_i(x)) \leq \epsilon(\theta_i)$ and $x \in N_i$ if and only if $CC(T_i(x)) > \theta_i$ where $B_n(x) = (T_i(x), \theta_i)$. Observe that B_n is a $n^{1/(4d)}$ -honest NC^0 reduction of Π_i to ϵ -GapMCSP.

There are two cases, depending on whether $N_i = \emptyset$ or not. If $N_i = \emptyset$, then $S = \{(T, \theta) : CC(T) \leq \theta\}$ is a solution to ϵ -GapMCSP such that every query to G_i is answered affirmatively. By the sturdiness of the reduction, the output of G_i can be replaced by the constant 1, and we let $\rho_i = \rho'_i$.

If $N_i \neq \emptyset$, then by Lemma 8, for all large n , $c_0(\Pi_i|_{\rho'_i}) \leq n^{1-3\delta}$. (The conditions of Lemma 8 are satisfied, since $(1/4d)(1-\alpha)/2^{d+1} > 3\delta$.) That is, there is a way to set at most $n^{1-3\delta}$ additional variables, thereby extending ρ'_i to obtain a new restriction ρ_i , such that for any string x of length n that agrees with ρ_i , $CC(T_i(x)) > \epsilon(\theta_i)$. Therefore, $S = \{(T, \theta) : CC(T) \leq \epsilon(\theta)\}$ is a solution to ϵ -GapMCSP such that every query to G_i is answered negatively. Hence, by the sturdiness of the reduction, gate G_i can be replaced by a

constant 0.

This completes stage i . Note that, in obtaining ρ_i from ρ_{i-1} we set an additional $O(\log n) + n^{1-3\delta} < n^{1-2\delta}$ variables.

Since $t < n^\delta$, we have that ρ_t has $m \geq n - tn^{1-2\delta} > n - n^\delta n^{1-2\delta} = n - n^{1-\delta} > n/2$ unset variables. Let C''_m be the circuit $C_n|_{\rho_t}$. Each oracle gate in C''_m has the property that the threshold that is computed is always no more than $n^{1/3d}$. Since the reduction is sturdy, the circuit still behaves correctly if each oracle gate is replaced by a circuit that computes MCSP exactly, and (as in the proof of Theorem 1.3 of [26]), instances of MCSP where θ is bounded by $n^{1/3d}/\log n$ can be computed by a DNF of size $2^{O(n^{1/3d})}$. Replacing each oracle gate by such a DNF yields a circuit of depth at most $d+1$, of size $2^{O(n^{1/3d})}$, computing PARITY, thereby violating the lower bound established in [15]. \square

If we consider the parameterized version of MCSP, rather than ϵ -GapMCSP, we obtain non-hardness even under $\leq_T^{\text{AC}^0}$ reductions.

Theorem 14. *Let $\ell(m) = o(g(m)/m^\delta)$ for some $1 > \delta > 0$. Then for any circuit family $\{C_n\}$ computing an $\leq_T^{\text{AC}^0}$ reduction of PARITY to MCSP $[\ell, g]$, there is an $\epsilon > 0$ such that, for all large n , C_n makes at least n^ϵ queries.*

Proof. Define the *oracle depth* of a gate G to be the largest number of oracle gates on any directed path ending with G .

Let $\{C_n\}$ be a circuit family computing an $\leq_T^{\text{AC}^0}$ reduction of PARITY to MCSP $[\ell, g]$. As above, we may assume that each C_n is sturdy, and that the subcircuit D_n consisting of those gates at oracle depth 1 consists of NC⁰ circuitry of depth at most d . Let k be the maximum oracle depth of any gate in $\{C_n\}$.

Here is a high-level overview of the rest of the proof: Similar to the proof of the preceding theorem, we construct a sequence of t restrictions ρ_1, \dots, ρ_t , so that in $C_n|_{\rho_i}$ the first i gates G_1, \dots, G_i can be replaced a constant. In this way, we transform C_n into a circuit on $n' \geq n/2$ input bits of oracle depth $k-1$.

We will first show that there is a value $\epsilon > 0$ (specified later) such that if C_n does not have at least n^ϵ gates at oracle depth 1, then C_n can be replaced by an $\leq_T^{\text{AC}^0}$ reduction of oracle depth $k-1$, by eliminating all of the oracle gates G_1, \dots, G_t at oracle depth 1.

Our argument proceeds in t stages, where oracle gate G_i is considered in stage i . At the start of stage i we have a partial restriction ρ_{i-1} that has at most $(i-1)n^{1-2\epsilon}$ bits set. Here is a detailed description of stage i :

Consider the circuit family B_n consisting of all of the gates that are on a path from any input to G_i . Note that B_n is an NC^0 circuit family computing some function $f_i(x) = T_i(x)$. Let $m = |T_i(x)|$. Also, although B_n sits inside of C_n (which is computing **PARITY**), the function f_i might not have any obvious connection to **PARITY**. By the end of the next paragraph, we will have identified some relevant properties of f_i .

We now aim to find a restriction of the inputs and a solution to $\text{MCSP}[\ell, g]$ for which the output of G_i is constant. Define $\Pi_i = (Y_i, N_i)$ to be the promise problem where for all x that agree with ρ_{i-1} we put $x \in Y_i$ if and only if $\text{CC}(T_i(x)) \leq \ell(m)$ and $x \in N_i$ if and only if $\text{CC}(T_i(x)) > g(m)$. Observe that by construction of Π_i , B_n is an NC^0 reduction of Π_i to $\epsilon\text{-GapMCSP}$.

There are two cases, depending on whether $N = \emptyset$ or not. If $N = \emptyset$, then $S = \{T : \text{CC}(T) \leq g(|T|)\}$ is a solution to $\text{MCSP}[\ell, g]$ such that every query to G_i is answered affirmatively. By the sturdiness of the reduction, the output of G_i can be replaced by the constant 1, and we let $\rho_i = \rho_{i-1}$.

If $N \neq \emptyset$, then, by Lemma 9, for all large n , $c_0(\Pi_i|_{\rho_{i-1}}) \leq n^{\epsilon'}$ for some $\epsilon' < 1$ that depends only on d and δ . That is, there is a way to set at most $n^{\epsilon'}$ additional variables, thereby extending ρ_{i-1} to obtain a new restriction ρ_i , such that for any string x of length n that agrees with ρ_i , $\text{CC}(T_i(x)) > \ell(m)$. Thus, $S = \{T : \text{CC}(T) \leq \ell(m)\}$ is a solution to $\text{MCSP}[\ell, g]$ such that every query to G_i is answered negatively. Therefore, by the sturdiness of the reduction, gate G_i can be replaced by a constant 0.

This completes stage i . Note that, in obtaining ρ_i from ρ_{i-1} we set an additional $n^{\epsilon'}$ variables.

It is now time to set the constant ϵ to be $1 - (\epsilon'/2)$.

Since $t < n^\epsilon$, we have that ρ_t has $r \geq n - tn^{\epsilon'} = n - n^{1-(\epsilon'/2)}n^{\epsilon'} = n - n^{1-(\epsilon'/2)} > n/2$ unset variables.

A minor complication arises when we want to repeat this argument inductively to reduce the oracle depth to $k - 2$ and so on. Namely, the constant ϵ' depends on the depth d of the NC^0 circuitry that feeds into the oracle gates at the bottom level of C_n . $C_n|_{\rho_t}$ has oracle depth $k - 1$, as desired, but it now has AC^0 circuitry feeding into the lowest level of oracle gates, and when we appeal to Lemma 4 to apply a random restriction to convert that AC^0 circuitry to NC^0 circuitry, the depth of the NC^0 circuitry increases to a depth that we can denote d_2 .

However, this problem is resolved by observing that the choice of ϵ' in Lemma 9 is monotone in the depth d . Thus, if we carry out the argument above, but pick ϵ' using the parameter d_2 instead of d when we appeal to Lemma 9, and then repeat the argument to reduce the oracle depth to $k - 2$, the parameters still work out. If we let d_3 be the depth of the NC^0 circuitry

that results by starting with C_n with depth- d NC^0 circuitry at the bottom, eliminating lowest level of oracle gates and applying a random restriction to obtain a circuit family of oracle depth $k - 1$ with NC^0 circuitry of depth d_2 at the bottom, and then repeating the process to obtain a circuit family of oracle depth $k - 2$ with NC^0 circuitry of depth d_3 at the bottom, then the argument above is sufficient to obtain a circuit family of depth $k - 3$, etc.

Thus, there is a choice of ϵ' that suffices to convert an arbitrary $\leq_{\text{T}}^{\text{AC}^0}$ reduction of oracle depth k (with fewer than n^ϵ oracle gates) to an AC^0 circuit computing parity on $n^{\Omega(1)}$ input bits, thereby obtaining the desired contradiction. \square

7 Open Questions

There remain several open questions. The true complexity of MCSP remains a mystery. We have made progress in understanding the hardness of an approximation to MCSP , but how far can Theorem 1 be extended? Can we prove non-hardness under general truth-table and Turing reductions? Can we reduce the gap in the theorem to some constant factor approximations? Does the impossibility result hold when AC^0 is replaced with, say, $\text{AC}^0[2]$ many-one reductions? Is MCSP hard for DET under $\leq_{\text{m}}^{\text{AC}^0}$ reductions? (Recall that the related problem MKTP is hard for DET under such reductions [7].)

Acknowledgments

Much of this work was done during the 2018 DIMACS REU program, which was organized by Lazaros Gallos, Parker Hund, and many others. During this time, R. I. and N. V. were supported by NSF grant CCF-1559855, and they were undergraduates at Rutgers University and Harvard University, respectively. Subsequently, R.I. was supported by an Akamai Presidential Fellowship. E. A. is supported in part by NSF grants CCF-1909216 and CCF-1514164. This work was done in part while E. A. was visiting the Simons Institute for the Theory of Computing. We would also like to thank Michael Saks, Shuichi Hirahara, Avishay Tal, and John Hitchcock for helpful discussions. Finally, we are grateful to our anonymous reviewers for suggestions on improving this paper's exposition.
