Abstract. Secure messaging schemes such as the Signal protocol rely on out-of-band channels to verify the authenticity of long-running communication. Such out-of-band checks however are only rarely actually performed by users in practice.

In this paper, we propose a new method for performing continuous authentication during a secure messaging session, without the need for an out-of-band channel. Leveraging the users' long-term secrets, our *Authentication Steps* extension guarantees authenticity as long as long-term secrets are not compromised, strengthening Signal's post-compromise security. Our mechanism further allows to detect a potential compromise of long-term secrets after the fact via an out-of-band channel.

Our protocol comes with a novel, formal security definition capturing continuous authentication, a general construction for Signal-like protocols, and a security proof for the proposed instantiation. We further provide a prototype implementation which seamlessly integrates on top of the official Signal Java library, together with bandwidth and storage overhead benchmarks.

Keywords: Secure messaging · Authentication · Compromise detection · Post-compromise security.

1 Introduction

The Signal end-to-end encrypted messaging protocol [20] is used by billions of people [28], in the Signal app itself and other messengers such as Facebook Messenger [11] and WhatsApp [26]. The security of encryption keys used in the Signal protocol relies on two composed cryptographic protocols. First, a Diffie–Hellman-style key exchange protocol involving long-term asymmetric keys (whose public part is distributed via a central Signal server) is used to derive a shared secret. This initial shared secret is then used by parties in Signal's Double Ratchet protocol [17] to derive symmetric keys, used to encrypt messages between the two communicating parties.

Signal's Security. There have been numerous analyses of the security of the Signal protocol, as has been recapitulated in [22], which show that security properties for messaging protocols come in a variety of flavours with different adversary powers and strengths.

For these analyses, models separate different types of secrets: *session secrets* (like ephemeral randomness or state), which are used throughout the Double Ratchet protocol, and *long-term secrets*, used only in the initial key agreement. Some [6,7] study the security of the Signal protocol in its entirety, including the X3DH key exchange. Others [1,2,10,13,15,18] focus exclusively on the ratcheting part of the protocol, thus considering only session secrets. Among other security properties, [6] and [1] confirm that against strong adversaries who control the network and can adaptively compromise session and long-term secrets, Signal offers forward secrecy (meaning that the secrecy of messages sent before a secret leakage are still secure) as well as post-compromise security [7] (meaning that after users exchange *unmodified* messages, security is restored or "healed").

As pointed out by [9], the definition of post-compromise security is quite restrictive in the sense that the adversary needs to remain completely passive for security to be restored. Indeed, if the adversary remains active after a state leakage and continuously injects forged messages, authenticity is never restored. [9] instead proposes a protocol relying on an out-of-band channel (like email, SMS, or an in-person meeting) to detect such active adversaries, leveraging additional *fingerprints* computed by the protocol and compared over the out-of-band channel. However, while detection clearly is a good step towards mitigating attacks, it does not prevent the actual attack from continuing.

Locking Out Active Adversaries. The question we are interested in for this work goes one step further:

Can we, post-compromise, lock out even
an active adversary from a messaging communication?

Clearly, the answer in general is: No. An active network adversary that fully compromises a user's device, including all session and long-term secrets can, by design, fully impersonate that user subsequently. Our angle to approach the above question is to distinguish (and thus better leverage), the difference between the use of session and long-term secrets in the Signal protocol.

More specifically, what if we can leverage that user long-term secrets are harder to compromise, e.g., due to stronger randomness sources or better protection in hardware? Indeed, messaging services like WhatsApp or Signal are now deployed [27] on devices which have access to secure hardware such as Trusted Platform Modules (TPM) in which long-term secrets can be stored more safely. Phones on the other hand can use smart-cards to store their long-term keys. A typical attack scenario are border searches, where a travelling user would need to give away their phone or laptop for analysis, risking the leak of their session secrets. An adversary could then remain an active Man-in-the-Middle (MitM), possibly on nation-controlled networks, yet long-term keys in smart cards or a

TPM might not have been leaked. Such a breach of authenticity can have a high impact in the case of Signal as sessions are typically months or years long.

We can then ask:

Can we, post-compromise, lock out even
an active adversary from a messaging communication
that compromised session, but not long-term secrets?

Notably, the answer for Signal is still: No. We will show how to, generically, turn this into a Yes.

1.1 Contributions

The main contributions of this paper are

1. a formal, game-based definition of *continuous authentication*, a post-compromise security property locking out active adversaries who have not compromised long-term secrets;
2. a demonstration that protocols similar to Signal do not meet the security requirement;
3. a *generic extension* for messaging protocols to provide them with provably-secure continuous authentication;
4. a prototype implementation of our extension for Signal and an *analysis and benchmark* of the overhead it introduces;
5. exposing a discrepancy between the post-compromise security by Signal's official library and what is claimed in the literature.

1.2 Further Related Work

The security of real secure messaging implementations is also evaluated in [8], with a focus on (de)synchronization. Somewhat similar to our setting, their analysis involves an adversary trying to break post-compromise security by impersonating a compromised user and finding discrepancies between the implementations and the formal specifications.

Similarly to our approach, [13] proposes a construction for secure messaging by signing message transcripts, focusing though on healing communication under *passive* attacks while we are interested to detect and prevent *active* attacks.

2 Continuous Authentication

This section presents what locking out an active adversary from a messaging communication formally means. The basis for this is a formal syntax, following [1], that captures generic *messaging schemes* that operate on an unreliable channel, derive an initial shared session secret using long-term keys and then derive further session secrets from previous state, new randomness and possibly long-term keys. This in particular encompasses the Signal Double Ratchet protocol.

We then put forward a game-based security definition for *continuous authentication*, which guarantees two core properties:

1. An active MitM adversary that compromised a user's communication state gets *locked out* of the communication *unless* it has also compromised the user's long-term secrets.
2. Users can correctly *decide whether* long-term secrets have been compromised in an active attack, via an out-of-band channel.

The first property captures the desired strengthening of messaging protocols. In the Double Ratchet protocol [17], all secrets are derived from prior established secret state (the so-called *root* and *chain* keys) and new randomness generated by the users (the Diffie–Hellman *ratchet* keys). The former is revealed in a full state compromise and the latter are unauthenticated and can hence be impersonated by the adversary. Therefore, an adversary can conserve its Man-in-the-Middle position indefinitely without being detected in-band.

The second property improves on a related issue: If long-term secrets *are* compromised, then security is not restored if users only close their current session and reopen a new one, but users will instead need to generate and distribute new long-term keys. This procedure however is cumbersome and typically involves manual effort, so ideally one would like to better know *when* it is indeed necessary. Continuous authentication offers such a checking mechanism, enabling users to only change their long-term secrets if they have indeed been leaked.

2.1 Messaging Schemes

A messaging scheme consists of several algorithms: The core algorithms, following [1], are used to create users (Register), initiate sessions between them (InitState) and let them send and receive messages (Send and Recv). Our definition supports an arbitrary number of users, but only two-party sessions (*i.e.*, no group chats).

In addition to the four core messaging algorithms, our formalization introduces StartAuth, a procedure which can be used to initiate an in-band authentication step[1] and DetectOOB, a procedure that compares the states of two session participants out-of-band and decides whether an adversary has used a long-term secret to avoid in-band detection.

Moreover, the session state contains an `auth` flag which is initially set to **None**. StartAuth is a special procedure which may set this flag to a value other than **None** to indicate that the party is currently performing an authentication step. An authentication step is *passed* once the `auth` flags of both communication parties are back to **None**.

In a session between two parties, we define an *epoch* as a flow of messages, sent by one party without receiving a reply by their peer. Epochs are numbered: even epochs correspond to messages sent by the initiator of the conversation and

[1] This procedure can leave the state unchanged if the messaging scheme, like the original Signal protocol, does not support in-band authentication.

odd epochs to messages sent by the responder. Within an epoch, messages are again numbered consecutively.

2.2 Security Game

We now present the formal security game capturing continuous authentication, represented in Definition 1.

The security game creates two users, Alice (A) and Bob (B), and lets the adversary interact with them using oracles to simulate a communication. As the final objective is to detect long-term secret compromise, long-term secrets are distributed honestly to parties. In contrast, medium-term secrets are generated by parties, but delivered on the communication channel, allowing the adversary to tamper with them. The adversary is active on the network and can corrupt devices, leaking their current state. The adversary can also compromise long-term secrets, which sets a flag *compromised* in the game, maintaining adversary knowledge within the game. When the adversary terminates, an out-of-band detection step (`detectTrial`, see Algorithm 1) is triggered.

The adversary breaks continuous authentication (we say the adversary "wins") by (1) fooling the out-of-band detection DetectOOB to think it compromised the long-term keys when it actually did not, or (2) injecting a message and successfully passing an authentication step ($passinj \neq \emptyset$), without being detected.

Note that our model conservatively grants the adversary more power than may seem reasonable in practice. In particular, the adversary can choose when in-band and out-of-band detection steps happen (by calling StartAuth and terminating). In practice, in-band detection steps may follow a predefined schedule, and out-of-band detection steps are performed at the discretion of users.

Oracles and Security Game. The adversary has access to the following oracles, with corresponding counterpart oracles for Bob:

- `createState-A` creates the initial state of Alice given some public information of Bob provided by the adversary.
- `transmit-A` takes a plaintext as input and simulates Alice sending it.
- `deliver-A` takes a ciphertext as input and simulates Alice receiving it.
- `corruptState-A` returns the current state of Alice.
- `auth-A` makes Alice request authentication.
- `corruptLTS-A` leaks Alice's long-term secret to the adversary.

For space reasons, we defer their formal definition to Fig. 2 in the appendix.

The security game itself and resulting security notions are defined as follows.

Definition 1. (Continuous Authentication). *Let $\mathcal{A}$ be a probabilistic polynomial-time adversary against a messaging scheme* `MS`*. It has access to oracles defined above, abbreviated as* $oracles_{\texttt{MS}}$*. The security game is given in Algorithm 1.*

```
game Detection-Game(A, MS):
    (LTI_A, LTS_A, MTI_A, MTS_A) <-$ MS.Register()
    (LTI_B, LTS_B, MTI_B, MTS_B) <-$ MS.Register()
    π_A, π_B ← None, None
    win ← False, closed ← False, compromised ← False
    trans_A, trans_B ← ∅, ∅
    inj_A, inj_B, authinj, passinj ← ∅, ∅, ∅, ∅
    A^{oracles_MS}(LTI_A, LTI_B, MTI_A, MTI_B)
    detectTrial()
    return win ∧ ¬closed
procedure detectTrial():
    assert(π_A ∧ π_B ∧ ¬π_A.auth ∧ ¬π_B.auth)
    d ← DetectOOB(π_A, π_B)
    if d ∧ ¬compromised:
        win ← True
    elif ¬d ∧ passinj ≠ ∅:
        win ← True
```

Algorithm 1: Security game capturing continuous authentication.

The advantage *of adversary* $\mathcal{A}$ *against the messaging scheme* **MS** *in the detection game is:*

$$\texttt{Adv}(\mathcal{A}) = Pr[\texttt{Detection-Game}(\mathcal{A}, \texttt{MS}) = 1].$$

The messaging scheme MS *is said to provide* continuous authentication *if for all efficient adversaries* $\mathcal{A}$, $\texttt{Adv}(\mathcal{A})$ *is small.*

The game defines internal variables to keep track of the communication and of the adversary's actions:

- (LTI_U, LTS_U) is the long-term information and secret of user U and π_U its state.
- *win* is a flag representing if the adversary has met the winning conditions.
- *closed* is a flag representing the state of the connection (if it is closed or not).
- *compromised* records if the adversary has compromised either of the parties' long-term secrets.
- $trans_U$ is a set holding ciphertexts created by a legitimate user U.
- inj_U is a set containing messages injected to user U (which user U accepted) that are yet to be authenticated. *authinj* is a set used during authentication steps which holds all injected messages currently being authenticated. *passinj* is a set containing all injected messages that successfully passed authentication.

Oracle Details. (See Appendix, Fig. 2 for the oracles' code-based definition.)

The `transmit-A/B` oracles are a wrapper around Send, which records ciphertexts created legitimately by users. Similarly, the `deliver-A/B` oracles are a wrapper around Recv which add injected ciphertexts to the *inj* sets.

When Alice starts an authentication step (which happens when she receives an authentication message or when `auth-A` is called), *authinj* is filled with all messages that were injected to her. Authenticated messages will be those she has received in the last epoch and before.

Whenever the adversary calls `deliver-A/B`, a function is called to check if the adversary has successfully injected a message and passed an authentication step. In that case, it adds the injected messages that were successfully authenticated in *passinj* and removes them from *authinj* and *inj* sets.

The *win* flag can only be set to **True** in the `detectTrial` function. This happens either if parties output **True** in the out-of-band detection step but the long-term secret was not compromised (users produced a false positive) or if they output **False** but communication was successfully tampered with and the authentication step passed (the attacker was successful at avoiding detection).

3 Introducing Authentication Steps

This section presents our proposed *Authentication Steps* protocol that generically extends messaging schemes to achieve continuous authentication.

Our extension introduces authentication steps that may happen regularly at defined epochs in a session or could be user-triggered. These authentication steps leverage long-term secrets. In Signal, the long-term secret of a user consists of their private identity key, a Diffie–Hellman exponent. The Authentication Steps protocol introduces a new type of long-term secret, which is a signing key $sigk^U$.[2]

The objectives of an authentication step are twofold:

1. to convince parties that they are communicating with the holder of their peer's private key, and
2. to detect tampering with messages since the last authentication step.

To that end, each party sends on the in-band channel their own view of the communication since the last authentication step. These messages are included alongside regular messages exchanged between users; as we will see, this allows the authentication steps to seamlessly be integrated on top of the existing Signal protocol.

In order to maintain forward secrecy, the additional information is derived from the (public) ciphertexts sent. To save space, intermediate computations compress those ciphertexts as they are sent or received. Those intermediate computations and an authentication step are illustrated in Fig. 1.

[2] In practice, Signal already re-uses the identity key to sign a user's medium-term public key using the XEdDSA [16] signature scheme; we therefore emphasize that an implementation may similarly reuse that identity key as the signing long-term key for our authentication steps extension. In practice, this means only maintaining a single long-term secret for both Signal and our Authentication Steps protocol.

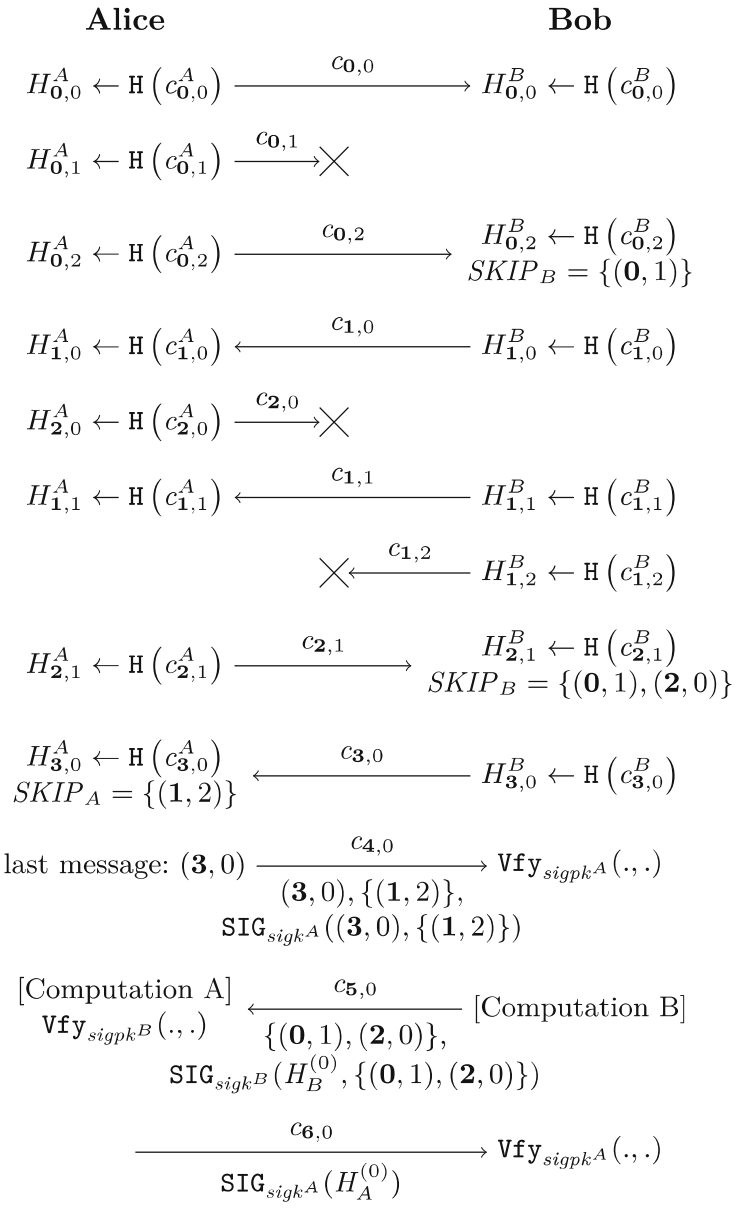

Fig. 1. An example execution of an authentication step. The actual authentication step is performed during epochs **4** to **6**, with authenticated messages from epoch **0** (epoch numbers in **boldface**). Additional data sent for those messages is included below arrows. For epochs **4** to **6**, $H_{\mathbf{i},j}$ hashes are still computed by both parties, but they are omitted in this figure as they concern the next authentication step. [Computation U] for $U \in \{A, B\}$ corresponds to the computation $H^{(0)}_U \leftarrow 0||\mathtt{H}\left(\varepsilon||H^U_{\mathbf{0},0}||H^U_{\mathbf{0},2}||H^U_{\mathbf{1},0}||H^U_{\mathbf{1},1}||H^U_{\mathbf{2},1}||H^U_{\mathbf{3},0}\right)$.

3.1 Recording Ciphertexts

In order to perform authentication steps, parties need to store the transcript of ciphertexts sent and received. The order in which messages are received is not relevant as reordering may be caused by the unreliable channel.

Instead of storing ciphertexts as sent, each party computes digests of those ciphertexts using a hash function and stores those in a dictionary. Concretely, for every sent or received message, each user U computes and stores $H^U_{i,j} = \mathtt{H}\left(c^U_{i,j}\right)$, where $\mathtt{H}$ is a cryptographic hash function and $c^U_{i,j}$ is the ciphertext corresponding to message j sent or received in epoch i by user U.

3.2 Authentication Steps

The stored (and hashed) ciphertexts are then used in the actual authentication step. An authentication step is a 3-pass message exchange and therefore requires three epochs to complete. In the following, an authentication step is described wlog. with Alice sending the first authentication message. Figure 1 illustrates an authentication step, performed in epochs 4 to 6.

The authentication step information is included in every message of the epoch. That way, the peer receives the authentication information at least once, as if they do not receive it, the epoch number will not increase. If authentication information is missing from a message where it should have been included, then the receiving party should dismiss the message.

In the first epoch, Alice sends the following additional authentication information (encrypted along with actual plaintext):

- the indexes of messages that she should have received from Bob, but did not, denoted $SKIP_A$,
- the index of the most recent message she has received from Bob, denoted *authidx*, and
- a signature $\mathtt{SIG}_{sigk^A}(authidx, SKIP_A)$ over both values.

This allows Bob to know which messages Alice wants to authenticate. When Bob receives this message, he first verifies the signature using Alice's signing public key. In case of success, Bob computes the following hash:

$$H_B^{(n_B)} = n_B || \mathtt{H}\left(H_B^{(n_B-1)} || \; ||_{(i,j)\in I_B^{(n_B)}} H^B_{i,j}\right),$$

where n_B is the number of authentication steps Bob has completed and $H_B^{(n_B-1)}$ the hash computed in the previous authentication step (with the convention $H_B^{(-1)} = \varepsilon$ the empty string). The concatenation happens in lexicographic order over $I_B^{(n_B)}$, the set of all messages sent and received by Bob since last authentication step and until message *authidx*, and excluding messages with an index contained in $SKIP_A$.

In the second epoch (with Bob sending messages), Bob sends the following information (along with the regular message plaintexts):

– the indexes of messages that he should have received from Alice, denoted $SKIP_B$, and
– a signature $\mathtt{SIG}_{sigk^B}(H_B^{(n_B)}, SKIP_B)$ over the hash computed and the indexes of missed messages.

When Alice receives Bob's message, she extracts the list $SKIP_B$ and computes the following hash:

$$H_A^{(n_A)} = n_A || \mathtt{H}\left(H_A^{(n_A-1)} || \; ||_{(i,j)\in I_A^{(n_A)}} H_{i,j}^A\right),$$

where, like for Bob, n_A is her number of completed authentication steps and $H_A^{(n_A-1)}$ is the previous hash (or $H_A^{(-1)} = \varepsilon$). Alice then checks the signature received from Bob, using Bob's public signing key, on data $(H_A^{(n_A)}, SKIP_B)$.

In the third epoch, Alice sends a signature $\mathtt{SIG}_{sigk^A}(H_A^{(n_A)})$ over her hashed collection of seen messages. When Bob receives it, he verifies the signature's validity on $H_B^{(n_B)}$ using Alice's signing public key.

If at some point a signature verification fails, the verifier closes the connection. Otherwise, Alice and Bob have *passed the authentication step.*

Deniable Signing. We emphasize that any unforgeable signature scheme can be used in the authentication step. In particular, to maintain Signal's deniability of the initial key agreement (cf. [25]), signatures can be generated using designated-verifier or 2-user ring signatures [14,19], similarly to their deployment in recent proposals for Signal-like deniable key exchanges [3,12,23,24].

3.3 Detecting Compromised Long-Term Secrets

In this setting, we assume that Alice and Bob have passed at least one authentication step. At each authentication step, parties derive a hash $H_A^{(n_A)}$ or $H_B^{(n_B)}$. Authentication steps succeed if the signatures over those hashes match.

On a high-level, users execute the following protocol: Using the out-of-band channel, parties compare the last hash they have computed (which they store in their state until the next authentication step) as well as the number of authentication steps performed. If the hash values and authentication steps counters match, the users output **False**, indicating that they do not detect long-term key compromise, otherwise they output **True**.

If no adversary tampers with the communication, then exchanged hashes would match. Conversely, hashes not matching means that an adversary is present. Moreover, as at least one authentication step has been successful, the adversary must have been able to forge a signature to avoid in-band detection, which indicates they know at least one long-term secret. We will formally prove these two properties of the Authentication Steps protocol next.

4 Security of the Authentication Steps Protocol

We now formally establish the continuous authentication security (as per Definition 1) of our Authentication Steps protocol extension given in Sect. 3.

Theorem 1. *Assuming a collision resistant hash function* H *and an existentially unforgeable signature scheme* $\mathcal{S}$*, the Authentication Steps protocol presented in Sect. 3 provides continuous authentication as per Definition 1.*

Formally, the advantage of any adversary $\mathcal{A}$ *in the detection game against the Authentication Steps protocol is bounded as follows:*

$$\mathit{Adv}(\mathcal{A}) \leq \mathit{Adv}^{coll}_{\mathcal{B}_1}(H) + 2 \cdot \mathit{Adv}^{EUF\text{-}CMA}_{\mathcal{B}_2}(\mathcal{S}),$$

for reduction adversaries $\mathcal{B}_1$ *and* $\mathcal{B}_2$ *given in the proof.*

The proof is separated into two cases:

1. users decide one of their long-term secrets is compromised when that is not the case; and
2. the adversary manages to inject a message and remain undetected.

Due to space restrictions, we defer the detailed proof to Appendix A, and only give a proof sketch here.

In Case 1, the adversary never corrupts the long-term secret, yet the parties decide that their long-term secret is compromised. Thus, the hashes that Alice and Bob exchanged at the end of the game must be different, but both Alice and Bob verified signatures hashes in the last authentication step. It follows then that either Alice or Bob received a signature that was not produced by their peer, and that the adversary must have successfully forged a message under one of their (non-compromised) signing key. This would violate EUF-CMA security of the signature scheme, leading to the $2 \cdot \mathtt{Adv}^{EUF\text{-}CMA}_{\mathcal{B}_2}(\mathcal{S})$ term in the theorem bound.

In Case 2, the adversary must have injected a message between Alice and Bob, but when Alice and Bob exchanged their hashes at the end of the game, the hash outputs matched. It follows that between Alice's or Bob's computations there must be a hash collision, leading to the $\mathtt{Adv}^{coll}_{\mathcal{B}_1}(H)$ term in the theorem bound.

5 Implementation and Benchmarks

We implemented a prototype of our Authentication Steps protocol which integrates seamlessly *on top* of the official Signal Java library.

Our full implementation can be found on GitHub[3], along with build instructions and our benchmarking tests.

[3] https://github.com/apoirrier/libsignal-java-authsteps

Space and Computation Overhead. Authentication steps require additional data to be computed and stored, such as the ciphertexts hashes between authentication steps.

The storage and bandwidth overhead is a function of the channel reliability and the average number of messages per authentication step, the latter being the more influential parameter. Indeed, the sender cannot know in advance which messages the peer has received, thus there is no alternative but storing every ciphertext hash individually.

As for computational overhead, computing the ciphertext hashes involves one hash invocation; additionally, at most one signature and one verification operation is performed per epoch. The signature scheme employed by Signal is XEdDSA [16]. Signing and verifying data typically requires the same amount of computation as the Diffie-Hellman key computation happening in asymmetric ratchet steps. Thus, the computational overhead is at most the same magnitude as the original computations in Signal.

Benchmarking the Space Overhead. In order to give an estimate on the space overhead induced by the Authentication Steps extension, we performed simulations of communication sessions to evaluate ciphertext size and state sizes. The message inputs for our simulations are taken from the National University of Singapore SMS Corpus [4,5], an SMS dataset composed of English text messages.

At the example of a 95%-reliable channel, our results show a mean increase of 43 bytes (+ 39%) in ciphertext size and 2.6 KB (+ 411%) in session state size compared to the unmodified Signal protocol. Overheads increase with longer communication epoch lengths and lower channel reliability.

This overhead can be optimized through the usage of trees (for instance Merkle trees) to store hashes, and compress them if consecutive sequences of messages are received. This optimization would be interesting to implement and benchmark, at the same time it would make the underlying analysis and notions more complex. Furthermore, this optimization can only be performed on the receiver's side, as the sender has no way to know which sent messages will eventually be received. Thus, the compression can only happen on at most half of the conversation, and the space optimisation is bound by a factor 2.

6 Observations on the Official Implementation

While implementing the proposed protocol, we found that the state deletion strategy in Signal's official Java implementation [21] is different from the strategy described in the formal analyses in the literature, such as [1] or [6], even if the latter claim to be based on the implementation. The official Signal specification [17] itself is unclear, and the strategy used in the implementation is implied but not made explicit.

In [1] or [6], post-compromise security kicks in after two epochs, which means that after two epochs of untampered communication after a state compromise, security is restored. This happens by the deletion of no longer necessary state

once an epoch ends. However, the Signal implementation deletes this state only 5 epochs later, which is a hardcoded value[4].

Based on this, we observe that the following attack is possible which demonstrates that the official Signal implementation achieves only slightly weaker post-compromise security than claimed in the literature. In the middle of a communication between Alice and Bob, an adversary leaks the state of Alice. Assume that during this epoch i, Alice sent n_i messages to Bob. The adversary can, by using the leaked state, create a valid ciphertext for message $(i, n_i + 1)$ (and even more messages).

Given the literature definition of post-compromise security, as the adversary remained passive security should be restored at epoch $i + 3$. However, with the Signal implementation, as Bob's state for epoch i is not yet deleted at epoch $i + 3$, the adversary can successfully inject messages (for epoch i) to Bob.

Note however that security is restored 5 epochs after compromise, therefore the implementation still guarantees a weaker post-compromise security property.

An Explanation of this Weaker Property, and Fixing it. The Signal implementation disregards the total number of messages sent in the previous epoch, which is included alongside messages, and instead keeps the chain key without computing in advance message keys for missed messages. This saves computation time and space as the keys are not computed if those messages never arrive while the immediate decryption property is still valid as the chain key is kept and message keys can be derived if needed.

To fix this, when a new receiving epoch begins, the value of the total number of messages can be used to derive all message keys for this epoch and then delete the chain key from the state. This recovers the strong post-compromise security as claimed in the literature.

7 Conclusion

Messaging protocols such as Signal that only use their long-term secrets for session initiation allow for state-compromising adversaries to permanently take over a connection as a Man-in-the-Middle. This paper offers a strengthened security notion, continuous authentication, which locks out an active adversary post-compromise who has not compromised long-term keys, and enables detection of long-term secret compromises using an out-of-band channel. Our Authentication Steps protocol extension generically enables this security in a provably-secure way, adding regular authentication steps in the protocol that leverages long-term keys to authenticate users and ensure no tampering has occurred. Moreover, an out-of-band protocol can be used on top of that to detect adversaries having used long-term secrets to avoid in-band detection.

[4] Cf. line 210 in https://github.com/signalapp/libsignal-protocol-java/blob/fde96d22004f32a391554e4991e4e1f0a14c2d50/java/src/main/java/org/whispersystems/libsignal/state/SessionState.java#L210.

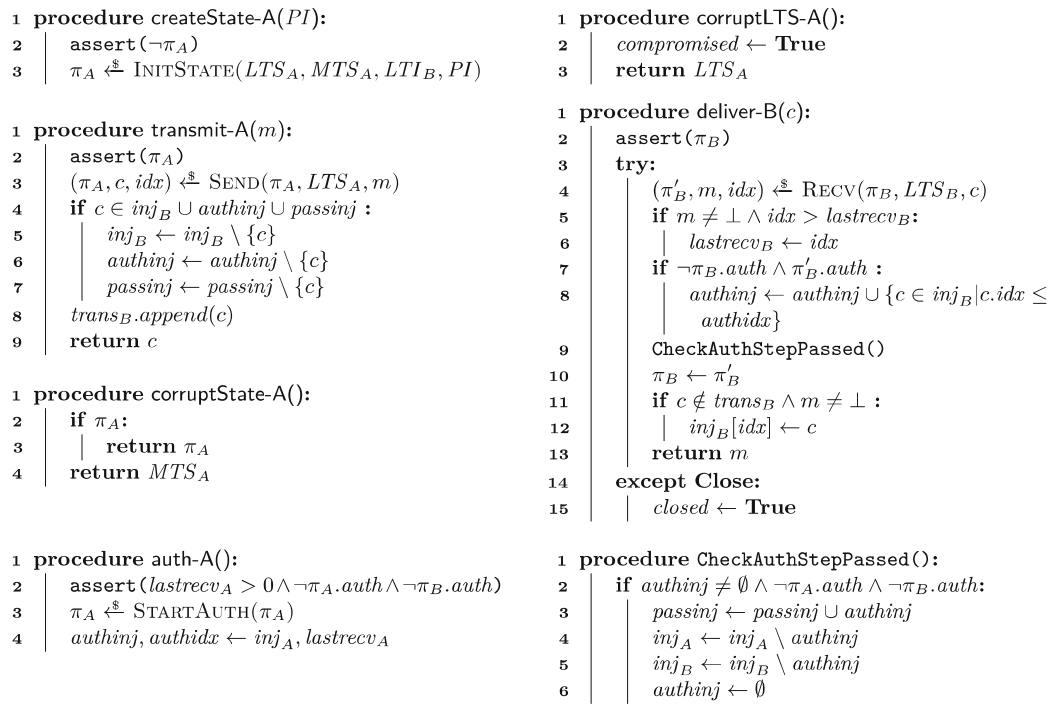

Fig. 2. Oracles available to the adversary in the continuous authentication security game (cf. Definition 1). The `MS.` prefixes for functions of the messaging scheme are omitted. The `CheckAuthStepPassed` function checks if the adversary succeeded in injecting a message which passed an authentication step. Each oracle has a counterpart whose implementation is similar by swapping A and B in the implementation.

We analysed the overhead introduced by authentication steps, benchmarking our prototype implementation which seamlessly integrates on top of the official Signal library. While implementing those benchmarks, we remarked that the official implementation has a weaker post-compromise security property than claimed in the literature.

While this paper focuses mainly on the Signal protocol, the concept of continuous authentication as well as the Authentication Steps protocol is generic. We envision that it can be adapted to other messaging protocols or protocols with long-lived connections, like TLS 1.3 resumption sessions, to provide stronger authenticity guarantees.

The Authentication Steps protocol strongly authenticates the entire transcript, even if the underlying channel is unreliable. Another interesting direction for future work is a conceivable reduced-overhead variant that only authenticates the key material (e.g., the ratchet keys in Signal) in every epoch. Such variant would still strengthen post-compromise security, yet in a weaker sense as it would not necessarily allow to detect the injection of messages at the end of compromised epochs, a property the Authentication Steps protocol provides.

A Security of the Authentication Steps Protocol

This section proves Theorem 1, which states that the Authentication Steps protocol is secure given the assumption that the underlying cryptographic primitives are secure, namely the hash function and the signature scheme. We denote $\mathtt{Adv}^{coll}_{\mathcal{A}}(H)$ the advantage of an adversary trying to find a collision for a hash function H and $\mathtt{Adv}^{EUF\text{-}CMA}_{\mathcal{A}}(\mathcal{S})$ the advantage of an adversary in the EUF-CMA (Existential UnForgeability in the Chosen Message Attack setting) game against a signature scheme $\mathcal{S}$.

False Positives and False Negatives. Before proving security of the Authentication Steps protocol from Sect. 3, we introduce several useful definitions.

Recall that from the specification, no authentication steps can overlap. Therefore, users will reject messages that start a new authentication step if they are currently performing one. We can thus number authentication steps from a user U's point of view from 1 to n_U.

For the actual theorem proof, we split the winning condition into two events, which we denote the false positive case and the false negative case, and use results from Propositions 1 and 2 to give an upper bound on their probability.

Definition 2. *Given an adversary $\mathcal{A}$ playing the security game of Definition 1, we define the following events:*

- W *is the event that the $\mathcal{A}$ wins the game,*
- FP *is the event that at the end of the game, $\neg closed \wedge \neg compromise \wedge d$ is true,*
- FN *is the event that at the end of the game, $\neg closed \wedge passinj \neq \emptyset \wedge \neg d$ is true.*

FP *and* FN *respectively stand for false positive and false negative.*

Proof (Proof of Theorem 1). Let $\mathcal{A}$ be an adversary in the game of Definition 1. Because of the implementation of the `detectTrial` function and because the *win* flag is only set in this function, it is immediate that $\mathrm{W} = \mathrm{FP} \sqcup \mathrm{FN}$ which are the events defined in Definition 2.

Therefore:

$$\mathtt{Adv}(\mathcal{A}) = \Pr[\mathrm{W}] = \Pr[\mathrm{FP}] + \Pr[\mathrm{FN}].$$

Moreover, Proposition 2 states that $\Pr[\mathrm{FP}] \leq 2 \cdot \mathtt{Adv}^{EUF\text{-}CMA}_{\mathcal{B}_2}(\mathcal{S})$ and Proposition 1 states that $\Pr[\mathrm{FN}] \leq \mathtt{Adv}^{coll}_{\mathcal{B}_1}(H)$, which proves the inequality.

A.1 Upper Bound for False Negatives

This section gives an upper bound on the probability $\Pr[\mathrm{FN}]$ that an adversary produces a false negative in the game. We first introduce Lemma 1 which is used to prove Proposition 2.

Lemma 1. *Let $\mathcal{A}$ be an adversary playing the security game of Definition 1 against the Authentication Steps protocol from Sect. 3.*

If $passinj \neq \emptyset$ at the end of the game, it means that there exists some user $U \in \{A, B\}$, an authentication step j for U and a message index $i \in I_U^{(j)}$ such that $c_i^A \neq c_i^B$ (where one of the ciphertext could be $\perp$ if the corresponding user has sent no ciphertext for index i).

Proof. In the following we consider an execution of the game which leads to $passinj \neq \emptyset$ at the end of the game.

Let i be the index of a ciphertext in $passinj$. $passinj$ is filled only in the `CheckAuthStepPassed` function (see Fig. 2) if $authinj$ is not empty.

$authinj$ is filled only at two places: at Line 4 of the `auth-A/B` oracle, or at Line 8 of `deliver-A/B` (see Fig. 2). For both cases, this happens when a user U enters an authentication step (wlog. we choose authentication step j), and message i comes from inj_U.

Message i has already been received because it is in inj_U when added to $authinj$, *i.e.*, when the authentication step begins, so it is not a skipped message. Moreover, $i \leq auth.authidx$ given the implementation of StartAuth.

$\pi_U.lastauth$ contains the index of the last message authenticated. As $authinj$ is cleared at the end of every authentication step, having the ciphertext corresponding to index i in $authinj$ means that it has not been authenticated in a previous authentication step. Moreover, messages coming before the previous authentication step are not decrypted, which means that necessarily $i > \pi_U.lastauth$.

This proves that for this authentication step j, $i \in [\pi_U.lastauth, authinfo.authidx]$ and not in U's skipped dictionary, which means $i \in I_U^{(j)}$.

Because $i \in inj_U$, it means U received and accepted ciphertext c_i^U (when it was added to inj_U). If V is the peer of U, then c_i^V (if it exists) cannot be equal to c_i^U because otherwise it would have been generated honestly by V and therefore removed from injected sets in lines 5 to 7 of `transmit-A/B` in Fig. 2, or never added to inj_U because in $trans_U$ (see Line 8 of `transmit-A` and Line 11 of `deliver-B` in Fig. 2). Therefore, $c_i^A \neq c_i^B$.

The following proposition gives an upper bound on the probability that the adversary produces a false negative.

Note that in the construction given in Sect. 3, hashes are used to save space for ciphertexts. However, if no hashes were used and transcripts of actual ciphertexts were stored instead, false negatives could never happen.

Proposition 1 (False Negatives). *Let $\mathcal{A}$ be an adversary in the detection game of Definition 1 playing against the Authentication Steps protocol presented in Section 3.*

Then $\Pr[\mathrm{FN}] \leq \mathbf{Adv}_{\mathcal{B}_1}^{coll}(H)$, *for a reduction adversary $\mathcal{B}_1$ constructed in the proof.*

Proof. Let $\mathcal{A}$ be an adversary producing event FN. Recall from Definition 2 that $\text{FN} = \neg \mathit{closed} \wedge \mathit{passinj} \neq \emptyset \wedge \neg d$.

In particular, *passinj* is not empty at the end of the game. According to Lemma 1, this implies the existence of an authentication step j_0 for user $V \in \{A, B\}$ and some index i such that $i \in I_V^{(j_0)}$ and $c_i^A \neq c_i^B$.

However, d is **False**. Given the computation of d in the DetectOOB procedure this means that $\pi_A.H_A^{(n_A)} = \pi_B.H_B^{(n_B)}$.

Recall that for any user U, $H_U^{(n_U)} = n_U || H_U^{(n_U-1)}$. In particular $n_A = n_B$ and Alice and Bob have seen the same number of authentication steps.

Hashes $H_U^{(j)}$ are computed as follows: $H_U^{(j)} \leftarrow \mathtt{H}\left(H_U^{(j-1)} \,||\, ||_{k \in \mathtt{sorted}(I_U^{(j)})} \pi_U.H_k^U\right)$ for any $j \geq 0$ and with $H_U^{(-1)} = \varepsilon$.

For any $j \geq 0$, if $H_A^{(j)} = H_B^{(j)}$, then there are only two possibilities:

1. either $H_A^{(j-1)} \,||\, ||_{k \in \mathtt{sorted}(I_A^{(j)})} \pi_A.H_k^A \neq H_B^{(j-1)} \,||\, ||_{k \in \mathtt{sorted}(I_B^{(j)})} \pi_B.H_k^B$;
2. either they are equal.

For the first case, because $H_A^{(j)} = H_B^{(j)}$ but the two inputs to the hash function are different, we have a hash collision.

The second case would induce a propagation property and yield $H_A^{(j-1)} = H_B^{(j-1)}$.

As the equality $H_A^{(j)} = H_B^{(j)}$ is true for the last authentication step, by induction we can deduce that either there is a hash collision or for all authentication step j:

$$||_{k \in \mathtt{sorted}(I_A^{(j)})} \pi_A.H_k^A = ||_{k \in \mathtt{sorted}(I_B^{(j)})} \pi_B.H_k^B.$$

This is true in particular for $j = j_0$. Recall that elements of $\pi_U.H^U$ are hashes of ciphertexts computed on sending and receiving.

As the hash function produces outputs of the same length, it means that there are exactly the same number of hashes in each concatenation. Moreover, $i \in I_V^{(j_0)}$ so one hash corresponds to the ciphertext with index i. Let's denote $H_V = \mathtt{H}(c_i^V)$ and $H_W = \mathtt{H}(c^W)$ the corresponding hashes (where H_W is at the same position in the concatenation that H_V but for the other user).

Because the concatenations are equal, $H_V = H_W$. However, $c^W \neq c_i^V$. Indeed, if we had $c^W = c_i^V$, then both would correspond to the same index i, but c^W is the version of ciphertext i sent by W and c_i^V is the version received by V. However, by definition of i, we necessarily have $c_i^A \neq c_i^B$ and therefore the equality is impossible. As $H_V = H_W$ but $c^W \neq c_i^V$, we have a hash collision.

Therefore, any case leading the adversary to a false negative shows that the adversary could produce an explicit hash collision, and therefore the reduction $\mathcal{B}_1$ from the detection game to the hash collision game is immediate.

This shows that $\Pr[\text{FN}] \leq \mathtt{Adv}_{\mathcal{B}_1}^{coll}(H)$.

A.2 Upper Bound for False Positives

This section gives an upper bound on the probability Pr [FP] that the adversary produces a false positive in the game.

Proposition 2 (False Positives). *Let $\mathcal{A}$ be an adversary in the detection game of Definition 1 playing against the Authentication Steps protocol of Sect. 3.*

Then $\Pr[\mathrm{FP}] \leq 2 \cdot \mathbf{Adv}^{EUF-CMA}_{\mathcal{B}_2}(\mathcal{S})$*, for a reduction adversary $\mathcal{B}_2$ constructed in the proof.*

Proof. Let $\mathcal{A}$ be an adversary producing event FP. Having $\neg$*compromise* means that $\mathcal{A}$ never calls the `corruptLTS-A/B` oracles. Moreover, $\neg$*closed* means the communication never closes, which means that signature verifications always succeed. We will build an adversary $\mathcal{B}_2$ for the EUF-CMA game against signature scheme $\mathcal{S}$ as a wrapper around $\mathcal{A}$, which acts as a challenger in the detection game for $\mathcal{A}$.

$\mathcal{B}_2$ creates two users Alice and Bob, but will embed a public key provided by the EUF-CMA challenger into one party's signing key-pair and use the signing oracle to generate signatures.

As user U_1 is entirely generated by $\mathcal{B}_2$, the adversary can simulate the oracles concerning U_1, and therefore they are similar to the oracles defined in Fig. 2.

$\mathcal{B}_2$ keeps track of signature forgeries. Every time $\mathcal{B}_2$ signs a message using the oracle provided by his challenger, $\mathcal{B}_2$ stores it. Moreover, every time a signature on the signing public key pk given by the EUF-CMA game is verified, $\mathcal{B}_2$ checks if the signature was produced by the signing oracle. If that is not the case, but the verification is successful, $\mathcal{B}_2$ stops and outputs the corresponding pair m^*, σ^*.

To simulate user U_0 whose private key is unknown, $\mathcal{B}_2$ can also use the original oracles, except for $\mathsf{transmit}{-}U_0$ which is the only oracle using U_0's private signing key in the SEND procedure. Recall that the `corruptLTS-A/B` oracles are not called by adversary $\mathcal{A}$ and therefore $\mathcal{B}_2$ does not need to simulate those oracles when the event FP happens. In order to create the signature, $\mathcal{B}_2$ can query their own challenger with message $\pi_{U_0}.auth$ to get the signature using U_0's private key. Therefore, $\mathcal{B}_2$ is correctly defined and can act as a challenger for $\mathcal{A}$.

Let's now prove that if $\mathcal{A}$ triggers the event FP, then $\mathcal{B}_2$ wins the EUF-CMA game with probability at least $\frac{1}{2}$.

During his last authentication step n, U_1 verified successfully a signature σ on $\pi_{U_1}.auth$ by using U_0's public signing key $sigpk^{U_0}$. $\pi_{U_1}.auth$ contains in particular $n_U = n$ and $H = H_1$ computed by U_1. Because U_0 and U_1 can number their authentication steps, they will produce at most one signature on an *auth* set having $n_U = n$. At the end of the game, parties output $d =$ **True**. From the implementation of DETECTOOB, this means that $\pi_A.H_A^{(n_A)} \neq \pi_B.H_B^{(n_B)}$. Given the definition of $\pi_U.H_U^{(n_U)}$ this means that during the last authentication step of each party:

$$\pi_A.n_A||\pi_A.auth.H \neq \pi_B.n_B||\pi_B.auth.H\,.$$

There are two disjoint possibilities:

1. either $\pi_A.n_A = \pi_B.n_B$ but $\pi_A.auth.H \neq \pi_B.auth.H$;
2. either $\pi_A.n_A \neq \pi_B.n_B$;

In Case 1, $\pi_A.n_A = \pi_B.n_B = n$ and $\pi_A.auth.H \neq \pi_B.auth.H$. Yet U_1's verification of σ succeeded on the data $\pi_{U_1}.auth$ which contains $n_U = n$ and $H = H_1$. However, as stated above U_0 can produce and sign at most one set $auth$ with $n_U = n$, and this set has $H = \pi_{U_0}.auth.H \neq \pi_{U_1}.auth.H = H_1$. Therefore, $\pi_{U_1}.auth$ was not submitted to the signing oracle, and yet σ verifies over $\pi_{U_1}.auth$, so $\mathcal{B}_2$ can output this forgery.

In Case 2, $\pi_A.n_A \neq \pi_B.n_B$. Recall that U_0 and U_1 are chosen uniformly at random at the beginning of the game. Because the signing key-pair and signatures are sampled and created in the same way in the detection game and in the reduction when using the signing oracle, $\mathcal{A}$ cannot distinguish which key-pair is used in the signing game. Therefore, with probability $\frac{1}{2}$, $\pi_{U_0}.n_{U_0} < \pi_{U_1}.n_{U_1}$.

In that case, U_0 cannot have signed a set $\pi_{U_0}.auth$ with $n_{U_0} = \pi_{U_1}.n_{U_1}$ as it has not yet reached the correct number of authentication steps. This once again yields a valid signature forgery.

Therefore, with probability at least $\frac{1}{2}$, if $\mathcal{A}$ triggers FP then $\mathcal{B}_2$ wins the EUF-CMA game. This leads to the upper bound $\Pr[\mathrm{FP}] \leq 2 \cdot \mathtt{Adv}^{EUF\text{-}CMA}_{\mathcal{B}_2}(\mathcal{S})$.
