# Strategic Planning through Model Checking of ATL Formulae

Wojciech Jamroga

Parlevink Group, University of Twente, Netherlands jamroga@cs.utwente.nl http://www.cs.utwente.nl/~jamroga

**Abstract.** Model checking of temporal logic has already been proposed for automatic planning. In this paper, we introduce a simple adaptation of the ATL model checking algorithm that returns a strategy to achieve given goal. We point out that the algorithm generalizes minimaxing, and that ATL models generalize traditional game trees. The paper ends with suggestions about other game theory concepts that can be transfered to ATL-based planning.

**Keywords:** Multi-agent systems, multi-agent planning, model checking.

#### 1 Introduction

Logic-based approaches to Artificial Intelligence seem to be presently undervalued by most AI practitioners. However, we believe that mathematical logic – while probably not the best tool for engineering – should still be important in AI research for at least two reasons. First, mathematical models provide a conceptual apparatus for *thinking* about systems, that can be as well used outside mathematical logic. The second reason is that creating a formal model of a problem makes one realize many (otherwise implicit) assumptions underlying his or her approach to this problem. Having made them explicit, one can strive to relax some of them and still use a part of the formal and conceptual machinery – instead of designing solutions completely ad hoc.

Model checking is an interesting idea that emerged from the research on logic in computer science. The model checking problem asks whether a particular formula  $\varphi$  holds in a particular model M. This seems especially useful in the case of dynamic or temporal logics, whose models can be interpreted as game models, transition systems, control flow charts, data flow charts etc. Moreover, model checking turns out to be relatively cheap in computational terms. It has been already proposed that the model checking of computation tree logic (CTL) formulae can be used for generating plans in deterministic as well as non-deterministic domains [6,7]. ATL is an extension of CTL that includes notions of agents, their abilities and strategies (conditional plans) explicitly in its models. Thus, ATL seems even better suited for planning, especially in multi-agent systems, which was already suggested in [8]. In this paper, we introduce a simple adaptation of

<sup>©</sup> Springer-Verlag Berlin Heidelberg 2004

the ATL model checking algorithm from [1] that – besides checking if a goal can be achieved – returns also an appropriate strategy to achieve it. We point out that this algorithm generalizes the well-known search algorithm of minimaxing, and that ATL models generalize turn-based transition trees from game theory. The paper ends with some suggestions about other game theory concepts that seem worth studying in the context of ATL.

# 2 Multi-agent Planning through ATL Model Checking

Alternating-time Temporal Logic ATL [1] is an extension of CTL [3], and inherits from the latter several operators for describing temporal properties of systems: A (for all paths), E (there is a path), O (at the next moment), O (sometime), O (always) and O (until). Typically, paths are interpreted as sequences of successive states of computations. An example CTL model (transition system), together with the tree of possible computations, is displayed in Figure 1. A CTL formula A Ohalt, for instance, expresses the property that the the system is bound to terminate (which is true if the initial state is either O0 or O1, but false for O1 and O2. Another formula, O2 in the system halts (which is true for all states except O4).

ATL replaces E and A with a class of cooperation modalities  $\langle\!\langle A \rangle\!\rangle$  (where A is a group of agents). The common-sense reading of  $\langle\!\langle A \rangle\!\rangle \Phi$  is: "The group of agents A have a collective strategy to enforce  $\Phi$  regardless of what all the other agents do". ATL models include a set of players  $\Sigma$ , a set of (global) system states Q, valuation of propositions  $\pi$  (specifying which propositions are true in which states), and decisions available to every player at each particular state; finally, a complete tuple of decisions and a state imply a deterministic transition according to the transition function  $\delta$ . We will be writing  $\delta(q, \sigma_A, \sigma_{\Sigma \setminus A})$  to denote the system transition from state q when the agents from A decide to proceed with (collective) action  $\sigma_A$ , and  $\sigma_{\Sigma \setminus A}$  is the collective choice from their opponents.

It is worth noting that the complexity of ATL model checking is linear in the number of transitions in the model and the length of the tested formula, so the checking should terminate in a sensible time even for *huge* models and formulae.

```
function plan(\varphi).
   Returns a subset of Q for which formula \varphi holds, together with a (conditional)
   plan to achieve \varphi. The plan is sought within the context of concurrent
   game structure S = \langle \Sigma, Q, \Pi, \pi, \delta \rangle.
case \varphi \in \Pi: return \{\langle q, - \rangle \mid \varphi \in \pi(q)\}
case \varphi = \neg \psi : P_1 := plan(\psi); return \{\langle q, - \rangle \mid q \notin states(P_1)\}
case \varphi = \psi_1 \vee \psi_2:
   P_1 := plan(\psi_1);
                              P_2 := plan(\psi_2);
   return \{\langle q, - \rangle \mid q \in states(P_1) \cup states(P_2)\}
case \varphi = \langle \langle A \rangle \rangle \bigcirc \psi: return pre(A, states(plan(\psi)))
case \varphi = \langle \langle A \rangle \rangle \Box \psi:
   P_1 := plan(true);
                               P_2 := plan(\psi); \quad Q_3 := states(P_2);
   while states(P_1) \not\subseteq states(P_2)
   do P_1 := P_2|_{states(P_1)}; P_2 := pre(A, states(P_1))|_{Q_3} od;
   return P_2|_{states(P_1)}
case \varphi = \langle\!\langle A \rangle\!\rangle \psi_1 \mathcal{U} \psi_2:
   P_1 := \emptyset; Q_3 := states(plan(\psi_1)); P_2 := plan(true)|_{states(plan(\psi_2))};
   while states(P_2) \not\subseteq states(P_1) do P_1 := P_1 \oplus P_2; P_2 := pre(A, states(P_1))|_{Q_3} od;
   return P_1
end case
```

**Fig. 2.** Adapted model checking algorithm for ATL formulae. Cases of  $\psi_1 \vee \psi_2$  and  $\langle\!\langle A \rangle\!\rangle \diamondsuit \psi$  are omitted, because the first can be re-written as  $\neg(\neg \psi_1 \vee \neg \psi_2)$ , and the latter as  $\langle\!\langle A \rangle\!\rangle true \mathcal{U}\psi$ .

### 2.1 Planning Algorithm

In this section, a simple modification of the ATL model checking algorithm [1] is proposed, as shown in Figure 2. Function pre is used here to go "one step back" while constructing a plan for some coalition of agents. Thus,  $pre(A, Q_1)$  takes as input a coalition A and a set of states  $Q_1 \subseteq Q$  and returns as output the set  $Q_2$  of all states such that when the system is in one of the states from  $Q_2$ , the agents A can cooperate and force the next state to be one of  $Q_1$  (together with A's collective choices that accomplish this). Function states(P) returns all the states for which plan P is defined.  $P_1 \oplus P_2$  refers to augmenting plan  $P_1$  with all new subplans that can be found in  $P_2$ ; finally  $P|_{Q_1}$  denotes plan P restricted to the states from  $Q_1$  only. More formally:

```
- pre(A, Q_1) = \{ \langle q, \sigma_A \rangle \mid \forall \sigma_{\Sigma \setminus A} \delta(q, \sigma_A, \sigma_{\Sigma \setminus A}) \in Q_1 \}; \\ - states(P) = \{ q \in Q \mid \exists_{\sigma} \langle q, \sigma \rangle \in P \}; \\ - P_1 \oplus P_2 = P_1 \cup \{ \langle q, \sigma \rangle \in P_2 \mid q \notin states(P_1) \}; \\ - P|_{Q_1} = \{ \langle q, \sigma \rangle \in P \mid q \notin Q_1 \}.
```

Note that the algorithm returns a (non-empty) plan only if the outmost operator of the checked formula is a cooperation modality (i.e. it specifies explicitly who is to execute the plan and what is the objective). In consequence, our approach to negation is not constructive: for  $\neg \langle \langle A \rangle \rangle \Phi$ , the algorithm will not return a strategy for the rest of agents to actually avoid  $\Phi$  (although  $\neg \langle \langle A \rangle \rangle \Phi$  implies that such a strategy exists). Similar remark applies to alternative, conjunction,

and nesting of strategic formulae. This approach is more natural than it seems at the first glance – even if the subformulae refer to the same set of agents for whom plans are needed. Consider, for instance, the transition system from Figure 1, and suppose that there is only one agent a in the system, who executes the transitions. Formula  $\langle\!\langle a \rangle\!\rangle \Box \text{start} \wedge \langle\!\langle a \rangle\!\rangle \diamondsuit \text{halt}$  holds in  $q_1$ ; however, it is hard to see what plan should be generated in this case. True, a has a plan to remain in  $q_1$  for ever, and he has a plan to halt the system eventually, but these are different plans and cannot be combined. Similarly,  $\langle\!\langle a \rangle\!\rangle \Box \langle\!\langle a \rangle\!\rangle \diamondsuit \text{win}$  holds in  $q_0$ , but it does not mean that a has a plan to win infinitely many times. He can always see a way to win; however, if he chooses that way, he will be unable to win again!

#### 2.2 Rocket Example

As an example, consider a modified version of the Simple Rocket Domain from [2]. The task is to ensure that a cargo eventually arrives in Paris (proposition atCP); there are three agents with different capabilities who can be involved, and a single rocket that can be used to accomplish the task. Initially, the cargo may be in Paris, at the London airport (atCL) or it may lie inside the rocket (inCR). Accordingly, the rocket can be moved between London (atRL) and Paris (atRP).

There are three agents: x who can load the cargo, unload it, or move the rocket; y who can unload the cargo or move the rocket, and z who can load the cargo or supply the rocket with fuel (action fuel). Every agent can also decide to do nothing at a particular moment (the nop – "no-operation" action). The agents act simultaneously. The "moving" action has the highest priority (so, if one agent tries to move the rocket and another one wants to, say, load the cargo, then only the moving is executed). "Loading" is effected when the rocket does not move and more agents try to load than to unload. "Unloading" works in a similar way (in a sense, the agents "vote" whether the cargo should be loaded or unloaded). If the number of agents trying to load and unload is the same, then the cargo remains where it was. Finally, "fueling" can be accomplished alone or in parallel with loading or unloading. The rocket can move only if it has some fuel (fuelOK), and the fuel must be refilled after each flight. We assume that all the agents move with the rocket when it flies to another place. The concurrent game structure for the domain is shown in Figure 3.

$$plan(\langle\!\langle x \rangle\!\rangle \diamond \texttt{atCP}) = \{\langle 9, - \rangle, \langle 10, - \rangle, \langle 11, - \rangle, \langle 12, - \rangle\} \tag{1}$$

$$plan(\langle\!\langle x,y\rangle\!\rangle \diamond \mathtt{atCP}) = \{\langle 2,x : load \cdot y : nop \rangle, \langle 6,x : move \cdot y : nop \rangle, \langle 7,x : unload \cdot y : unload \rangle, \tag{2}$$

$$\langle 8, x : unload \cdot y : unload \rangle, \langle 9, - \rangle, \langle 10, - \rangle, \langle 11, - \rangle, \langle 12, - \rangle \}$$

$$plan(\langle\langle x,z\rangle\rangle \diamond \texttt{atCP}) = \{\langle 1,x:load \cdot z:load \rangle, \langle 2,x:load \cdot z:load \rangle, \langle 3,x:nop \cdot z:fuel \rangle, \\ \langle 4,x:move \cdot z:nop \rangle, \langle 5,x:load \cdot z:fuel \rangle, \langle 6,x:move \cdot z:nop \rangle, \\ \langle 7,x:unload \cdot z:nop \rangle, \langle 8,x:unload \cdot z:nop \rangle, \langle 9,-\rangle, \langle 10,-\rangle, \langle 11,-\rangle, \langle 12,-\rangle \}$$

Plans to eventually achieve at CP – for x alone, x with y, and x with z, respectively – are shown above. In the first case, x cannot guarantee to deliver

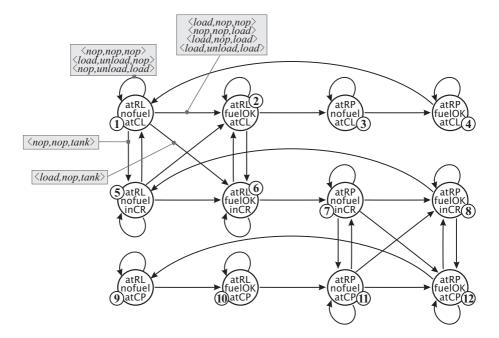

Fig. 3. A version of the Simple Rocket Domain. States of the system are labeled with natural numbers. All the transitions for state 1 (the cargo and the rocket are in London, no fuel in the rocket) are labeled. Output of agents' choices for other states is analogous.

the cargo to Paris (unless the cargo already is there), because y and z may prevent him from unloading the goods (2). The coalition of x and y is more competent: they can, for instance, deliver the cargo from London if only there is fuel in the rocket (2). However, they have no infallible plan for the most natural case when 1 is the initial state. Finally,  $\{x,z\}$  have an effective plan for any initial situation (3).

#### 2.3 Minimaxing as Model Checking

It is easy to see that the algorithm from Figure 2 can be used for emulating the well known search algorithm of minimaxing. To find the best plan for A, we should label the final positions with the payoff values  $p_1, p_2, ...$ , then check which  $plan(\langle\langle A \rangle\rangle \diamond p_i)$  returns a decision for the initial state, and pick the one for maximal  $p_i$ . The resulting procedure is still linear in the number of states, transitions and different payoff values. Note that the algorithm proposed here is more general than the original minimaxing: the latter can be applied only to finite turn-based game trees (i.e. systems in which the number of states is finite, there are no cycles, and players cannot act simultaneously), while the model checking-based approach deals also with models in which players act in parallel, and with infinite trees that can be generated by a finite transition system.

Let us also observe that the planning algorithm, proposed in this paper, looks for a plan that must be successful against every line of events – hence the algorithm generalizes minimaxing in zero-sum (i.e. strictly competitive) games. It can be interesting to model the non-competitive case within the scope of ATL as well: while checking  $\langle\!\langle A \rangle\!\rangle \varphi$ , the opponents  $\Sigma \setminus A$  may be assumed different goals than just to prevent A from achieving  $\varphi$ . Then, assuming optimal play from  $\Sigma \setminus A$ , we can ask whether A have a strategy to enforce  $\varphi$  provided that  $\Sigma \setminus A$  intend (or desire) to bring about  $\psi$ .

#### 3 Conclusions and Future Work

In this paper, an adaptation of ATL model checking is proposed. The algorithm looks for infallible conditional plans to achieve objectives that can be defined via ATL formulae. The algorithm generalizes minimaxing in zero-sum games, extending it to (possibly infinite) games in which agents can act in parallel.

It seems that the link between model checking and minimaxing can be exploited to enrich the framework of ATL, too. First (as already mentioned in the previous section), ATL might be extended so that it can be used to model non-competitive games. Next, efficient pruning techniques exist for classical minimaxing – it may be interesting to transfer them to ATL model checking. Moreover, game theory has developed more sophisticated frameworks, like games with incomplete information and games with probabilistic outcomes (including temporal models, best defense criteria etc.). Investigation of similar concepts in the context of ATL can prove worthwhile, and lead to new research questions, concerning phenomena like non-locality [4] and design of efficient suboptimal algorithms [5] in the scope of logics for multi-agent systems.
