Abstract. The OAEP construction is already 10 years old and well-established in many practical applications. But after some doubts about its actual security level, four years ago, the first efficient and provably IND-CCA1 secure encryption padding was formally and fully proven to achieve the expected IND-CCA2 security level, when used with any trapdoor permutation. Even if it requires the partial-domain one-wayness of the permutation, for the main application (with the RSA permutation family) this intractability assumption is equivalent to the classical (full-domain) one-wayness, but at the cost of an extra quadratic-time reduction. The security proof which was already not very tight to the RSA problem is thus much worse.

However, the practical optimality of the OAEP construction is two-fold, hence its attractivity: from the efficiency point of view because of two extra hashings only, and from the length point of view since the ciphertext has a minimal bit-length (the encoding of an image by the permutation.) But the bandwidth (or the ratio ciphertext/plaintext) is not optimal because of the randomness (required by the semantic security) and the redundancy (required by the plaintext-awareness, the sole way known to provide efficient CCA2 schemes.)

At last Asiacrypt '03, the latter intuition had been broken by exhibiting the first IND-CCA2 secure encryption schemes without redundancy, and namely without achieving plaintext-awareness, while in the random-oracle model: the OAEP 3-round construction. But this result achieved only similar practical properties as the original OAEP construction: the security relies on the partial-domain one-wayness, and needs a trapdoor permutation, which limits the application to RSA, with still a quite bad reduction.

This paper improves this result: first we show the OAEP 3-round actually relies on the (full-domain) one-wayness of the permutation (which improves the reduction), then we extend the application to a larger class of encryption primitives (including ElGamal, Paillier, etc.) The extended security result is still in the random-oracle model, and in a relaxed CCA2 model (which lies between the original one and the replayable CCA scenario.)

P.J. Lee (Ed.): ASIACRYPT 2004, LNCS 3329, pp. 63–77, 2004.

1 Introduction

The OAEP construction [4, 12, 13] is now well-known and widely used, since it is an efficient and secure padding. However, the latter property had been recently called into question: indeed, contrarily to the widely admitted result, the security cannot be based on the sole one-wayness of the permutation [28], but the partial-domain one-wayness [12, 13]. For an application to RSA, the main trapdoor one-way permutation, the two problems are equivalent, but the security reduction is much worse than believed, because of a quadratic reduction between the two above problems.

There is also a second drawback of the OAEP construction, since its use is limited to permutations. It can definitely not apply to any function, as tried and failed on the NTRU primitive [15].

Finally, the optimality, as claimed in the name of the construction, is ambiguous and not clear: from the efficiency point of view, the extra cost for encryption and decryption is just two more hashings which is indeed quite good. But the most important optimality was certainly from the length point of view: the ciphertext is just an image by the permutation, and thus the shortest as possible. However, another important parameter is the bandwidth, or the ratio ciphertext/plaintext, which is not optimal: the construction requires a randomness over $2k$ bits for a semantic security in 2^{-k}, and redundancy over k bits for preventing chosen-ciphertext attacks (plaintext-awareness): the ciphertext is thus at least $3k$ bits as large as the plaintext.

1.1 Related Work

Right after the Shoup's remark about the security of OAEP [28], several alternatives to OAEP have been proposed: OAEP+ (by Shoup himself) and SAEP, SAEP+ (by Boneh [6]) but either the bandwidth, or the reduction cost remain pretty bad. Furthermore, their use was still limited to permutations.

About generic paddings applicable to more general encryption primitives, one had to wait five years after the OAEP proposal to see the first efficient suggestions: Fujisaki–Okamoto [10, 11] proposed the first constructions, then Pointcheval [23] suggested one, and eventually Okamoto–Pointcheval [18] introduced the most efficient construction, called REACT. However, all these proposals are far to be optimal for the ciphertext size. They indeed apply, in the random-oracle model, the general approach of symmetric and asymmetric components integration [27]: an ephemeral key is first encrypted using key-encapsulation, then this key is used on the plaintext with a symmetric encryption scheme (which is either already secure against chosen-ciphertext attacks, or made so by appending a MAC – or a tag with a random oracle, for achieving plaintext-awareness.)

Plaintext-awareness [4, 3] was indeed the essential ingredient to achieve IND-CCA2 security in the random-oracle model: it makes the simulation of the decryption oracle quite easy, by rejecting almost all the decryption queries, unless the plaintext is clearly known. But this property reduces the bandwidth since

"unnecessary" redundancy is introduced. Randomness is required for the semantic security, but this is the sole mandatory extra data for constructing a secure ciphertext. At last Asiacrypt [21], the first encryption schemes with just such a randomness, but no redundancy, has been proposed: plaintext-awareness is no longer achieved, since any ciphertext is valid and corresponds to a plaintext. But this does not exclude the IND-CCA2 security level. In that paper [21], we indeed proved that an extension of OAEP, with 3 rounds but without redundancy, provides an IND-CCA2 secure encryption scheme, with any trapdoor permutation, but again under the partial-domain one-wayness. Hence a bad security reduction.

Note 1. The classical OAEP [4] construction can be seen as a 2-round Feistel network, while our proposal [21] was a 3-round network, hence the name *OAEP 3-round*. By the way, one should notice that SAEP [6] can be seen as a 1-round Feistel network.

1.2 Achievements

In this paper, we address the two above problems: the bad security reduction of the OAEP constructions, because of the need of the intractability of the partial-domain one-wayness; and the restriction to permutations.

First, we show that, contrarily to the OAEP (2-round) construction which cannot rely on the (full-domain) one-wayness, the OAEP 3-round simply requires the (full-domain) one-wayness: because of the third round, the adversary looses any control on the r value. It is not able to make ciphertexts with the same r, without querying it.

Then, we extend the application of OAEP 3-round to a larger class of encryption primitives: it applies to any efficiently computable probabilistic injection $f : \mathrm{E} \times \mathrm{R} \to \mathrm{F}$, which maps any $x \in \mathrm{E}$ into F in a probabilistic way according to the random string $\rho \in \mathrm{R}$. We need this function to be one-way: given $y \in \mathrm{F}$, it must be hard to recover $x \in \mathrm{E}$ (we do not mind about the random string ρ); this probabilistic function also needs to satisfy uniformity properties which are implied by a simple requirement: f is a bijection from $\mathrm{E} \times \mathrm{R}$ onto F. Some additional restrictions will appear in the security proof:

- we cannot really consider the CCA2 scenario, but a relaxed one denoted RCCA, which is between the usual one and the replayable CCA2 introduced last year [7] and considered enough in many applications.
- the simulation will need a decisional oracle which checks whether two elements in F have the same pre-images in E. The security result will thus be related to the well-known gap-problems [19, 18].

This extension allows *almost* optimal bandwidths for many very efficient asymmetric encryption schemes, with an IND-RCCA security level related to gap-problems (e.g. an ElGamal variant related to the Gap Diffie-Hellman problem.) Note that the application to trapdoor one-way permutations like RSA results in a much more efficient security result, and provides an IND-CCA2 encryption scheme under the sole one-wayness intractability assumption.

This paper is then organized as follows: in the next section, we review the classical security model for asymmetric encryption, and present our new CCA-variant. In section 3, we present the OAEP 3-round construction for any probabilistic injection, with some concrete applications. The security result is presented and proven in section 4.

2 Security Model

In this section, we review the security model widely admitted for asymmetric encryption. Then, we consider some relaxed CCA-variants. First, let us briefly remind that a public-key encryption scheme $\mathcal{S}$ is defined by three algorithms: the key generation algorithm $\mathcal{K}(1^k)$, which produces a pair of matching public and private keys $(\mathsf{pk}, \mathsf{sk})$; the encryption algorithm $\mathcal{E}_{\mathsf{pk}}(m; r)$ which outputs a ciphertext c corresponding to the plaintext $m \in \mathcal{M}$, using random coins $r \in \mathcal{R}$; and the decryption algorithm $\mathcal{D}_{\mathsf{sk}}(c)$ which outputs the plaintext m associated to the ciphertext c.

2.1 Classical Security Notions

Beyond *one-wayness*, which is the basic security level for an encryption scheme, it is now well-admitted to require *semantic security* (*a.k.a. polynomial security* or *indistinguishability of encryptions* [14], denoted IND): if the attacker has some *a priori* information about the plaintext, it should not learn more with the view of the ciphertext. More formally, this security notion requires the computational indistinguishability between two messages, chosen by the adversary, one of which has been encrypted, which one has been actually encrypted with a probability significantly better than one half: the advantage $\mathsf{Adv}^{\mathsf{ind}}_{\mathcal{S}}(\mathcal{A})$, where the adversary $\mathcal{A}$ is seen as a 2-stage Turing machine (A_1, A_2), should be negligible, where $\mathsf{Adv}^{\mathsf{ind}}_{\mathcal{S}}(\mathcal{A})$ is formally defined as

$$2 \times \Pr\left[\begin{array}{l}(\mathsf{pk}, \mathsf{sk}) \leftarrow \mathcal{K}(1^k), (m_0, m_1, s) \leftarrow A_1(\mathsf{pk}),\\ b \stackrel{R}{\leftarrow} \{0,1\}, c = \mathcal{E}_{\mathsf{pk}}(m_b) : A_2(m_0, m_1, s, c) = b\end{array}\right] - 1.$$

Stronger security notions have also been defined thereafter (namely the *non-malleability* [8]), but we won't deal with it since it is similar to the semantic security in several scenarios [3, 5].

On the other hand, an attacker can use many kinds of attacks, according to the available information: since we are considering asymmetric encryption, the adversary can encrypt any plaintext of its choice with the public key, hence the basic *chosen-plaintext attack*. But the strongest attack is definitely when the adversary has an unlimited access to the decryption oracle itself, *adaptive chosen-ciphertext attacks* [25], denoted CCA or CCA2 (by opposition to the earlier *lunchtime attacks* [17], denoted CCA1, where this oracle access is limited until the challenge is known.) From now, we simply use CCA instead of CCA2 since we focus on adaptive adversaries.

The strongest security notion that we now widely consider is the *semantic security against adaptive chosen-ciphertext attacks* denoted IND-CCA —where the adversary just wants to distinguish which plaintext, between two messages of its choice, had been encrypted; it can ask any query to a decryption oracle (except the challenge ciphertext).

2.2 Relaxed CCA-Security

First, at Eurocrypt '02, An *et al* [1] proposed a "generalized CCA" security notion, where the adversary is restricted not to ask, to the decryption oracle, ciphertexts which are in *relation* with the challenge ciphertext. This relation must be an equivalence relation, publicly and efficiently computable, and decryption-respecting: if two ciphertexts are in relation, they necessarily encrypt identical plaintexts. This relaxation was needed in that paper, so that extra bits in the ciphertext, which can be easily added or suppressed, should not make the scheme theoretical insecure, while its security is clearly the same from a practical point of view.

More recently, another relaxation (an extra one beyond the above one) has been proposed by Canetti *et al* [7]: informally, it extends the above relation to the (possibly non-computable) equality of plaintexts. More precisely, if the adversary asks for a ciphertext c to the decryption oracle, c is first decrypted into m. Then, if m is one of the two plaintexts output in the first stage by the adversary, the decryption oracle returns test, otherwise the actual plaintext m is returned. They called this variant the "replayable CCA" security. They explain that this security level, while clearly weaker than the usual CCA one, is enough in most of the practical applications. The classical CCA security level is indeed very strong, *too strong* for the same reasons as explained above for the first relaxation.

In this paper, we could work with the latter relaxation, the "replayable CCA" scenario. But for a simpler security proof, as well as a more precise security result (with nice corollaries for particular cases, such as the RSA one) we restrict it a little bit into the "relaxed CCA" scenario, denoted RCCA. A scheme which is secure in this scenario is trivially secure in the "replayable CCA" one, but not necessarily in the "generalized CCA" or the usual CCA scenario. The actual relations between these scenarios depend on the way the random string is split. In the formal notation of the encryption algorithm, we indeed split the randomness in two parts r and ρ: $c = \mathcal{E}_{\mathsf{pk}}(m; r, \rho)$. The encryption algorithm is thus a function from $\mathcal{M} \times \mathcal{R} \times \mathrm{R}$ into the ciphertext set. We know that for being an encryption scheme, this function must be an injection with respect to $\mathcal{M}$ (several elements in $\mathcal{M} \times \mathcal{R} \times \mathrm{R}$ can map to the same ciphertext, but all these elements must project uniquely on $\mathcal{M}$: the plaintext.) In our new relaxation, we split the randomness in $\mathcal{R} \times \mathrm{R}$ so that this function is also an injection with respect to $\mathcal{M} \times \mathcal{R}$.

Let us assume that the challenge ciphertext is $c^\star = \mathcal{E}_{\mathsf{pk}}(m^\star; r^\star, \rho^\star)$. Let us consider the ciphertext $c = \mathcal{E}_{\mathsf{pk}}(m; r, \rho)$. According to the above comment, $(m^\star, r^\star)$ and (m, r) are uniquely defined from $c^\star$ and c respectively, while $\rho^\star$ and ρ may not be unique. Upon receiving c, the *relaxed decryption oracle* first checks whether $(m^\star, r^\star) = (m, r)$ in which case it outputs test. Otherwise, it outputs m.

Definition 2 (Relaxed CCA). *In the "relaxed CCA" scenario, an adversary has an unlimited access to the relaxed decryption oracle.*

Property 3. Security in the "relaxed CCA" scenario implies security in the "replayable CCA" one.

Proof. As already noticed, this is a trivial relation, since the decryption oracle in the latter scenario can be easily simulated by the relaxed decryption oracle: if its output is test, this value is forwarded, else the returned plaintext m is compared to the output of the adversary at the end of the first stage. According to the result of the comparison, either a test-answer is also given (if $m \in \{m_0, m_1\}$), or m.

This property was just to make clear that we do not relax more the CCA security, but still keep it beyond what is clearly acceptable for practical use. Namely, note that if R is the empty set, then the RCCA scenario is exactly the usual CCA one: if f is a permutation from E onto F (the RSA case.)

3 OAEP 3-Round: A General and Efficient Padding

3.1 The Basic Primitive

Our goal is to prove that OAEP 3-round can be used with a large class of one-way functions. More precisely, we need an injective *probabilistic* trapdoor one-way function family $(\varphi_{\mathsf{pk}})_{\mathsf{pk}}$ from a set E_{pk} to a set F_{pk}, respectively to the index pk: almost any encryption primitive, where the plaintext set is denoted E_{pk} and the ciphertext set is denoted F_{pk}, is fine: for any parameter pk (the public key), there exists the inverse function ψ_{sk} (where sk is the private key) which returns the pre-image in E_{pk}. An injective *probabilistic* trapdoor one-way function f from E to F is actually a function $f : \mathrm{E} \times \mathrm{R} \to \mathrm{F}$, which takes as input a pair (x, ρ) and outputs $y \in \mathrm{F}$. The element x lies in E and is the important input, ρ is the random string in R which makes the function to be probabilistic. Injectivity means that for any y there is at most one x (but maybe several ρ) such that $y = f(x, \rho)$. The function g which on input y outputs x is the inverse of the probabilistic function f. Clearly, we need the function f to be efficiently computable, but the one-wayness means that computing the unique x (if it exists) such that $y = f(x, \rho)$ is intractable (unless one knows the trapdoor g.) These are the basic requirement for an asymmetric encryption primitive. But for our construction to work, we need two additional properties:

- the function $f : \mathrm{E} \times \mathrm{R} \to \mathrm{F}$ is a bijection;
- without knowing the trapdoor, it is intractable to invert f in E, even for an adversary which has access to the decisional oracle $\mathsf{Same}_f(y, y')$ which answers whether $g(y) = g(y')$.

The latter property is exactly the "gap problem" notion, which is defined by the following success probability $\mathsf{Succ}_f^{\mathsf{gap}}(t, q)$, for any adversary $\mathcal{A}$ whose

running time is limited by t, and the number of queries to the decisional oracle Same_f is upper-bounded by q:

$$\mathsf{Succ}_f^{\mathsf{gap}}(t,q) = \max_{\mathcal{A}}\{x \stackrel{R}{\leftarrow} \mathrm{E}, \rho \stackrel{R}{\leftarrow} \mathrm{R}, y = f(x,\rho) : \mathcal{A}^{\mathsf{Same}_f}(y) = x\}.$$

For a family of functions, this success probability includes the random choice of the keys in the probability space, and assumes the inputs randomly drawn from the appropriate sets, hence the notation $\mathsf{Succ}_{\varphi}^{\mathsf{gap}}(t,q)$ for a family $(\varphi_{\mathsf{pk}})_{\mathsf{pk}}$.

3.2 Examples

Let us see whether the two above additional properties are restrictive or not in practice:

- The first example is clearly the RSA permutation [26], where for a given public key $\mathsf{pk} = (n,e)$, the sets are $\mathrm{E} = \mathrm{F} = \mathbb{Z}_n^\star$ and R is the empty set. Then, this is clearly an injective (but deterministic) function, which is furthermore a bijection. Because of the determinism, the decisional oracle $\mathsf{Same}(y,y')$ simply checks whether $y = y'$: the gap problem is thus the classical RSA problem.
- The goal of our extension of OAEP is to apply it to the famous ElGamal encryption [9] in a cyclic group $\mathbb{G}$ of order q, generated by g. Given a public key $\mathsf{pk} = y \in \mathbb{G}$, the sets are $\mathrm{E} = \mathbb{G}$, $\mathrm{R} = \mathbb{Z}_q$ and $\mathrm{F} = \mathbb{G} \times \mathbb{G}$: $\varphi_y(x,\rho) = (g^\rho, x \times y^\rho)$, which is a probabilistic injection from E onto F, and a bijection from $\mathrm{E} \times \mathrm{R}$ onto F. About the decisional oracle, it should check, on inputs $(a = g^\rho, b = x \times y^\rho)$ and $(a' = g^{\rho'}, b' = x' \times y^{\rho'})$, whether $x = x'$, which is equivalent to decide whether $(g, y, a'/a = g^{\rho'-\rho}, b'/b = (x'/x) \times y^{\rho'-\rho})$ is a Diffie-Hellman quadruple: the gap problem is thus the well-known Gap Diffie-Hellman problem [18, 19].
- One can easily see that the Paillier's encryption [20] also fits this formalism.

3.3 Description of OAEP 3-Round

Notations and Common Parameters. For a simpler presentation, and an easy to read analysis, we focus on the case where $\mathrm{E} = \{0,1\}^n$ (is a binary set). A similar analysis as in [21] could be performed to deal with more general sets. On the other hand, any function can be mapped into this formalism at some low cost [2].

The encryption and decryption algorithms use three hash functions: $\mathcal{F}$, $\mathcal{G}$, $\mathcal{H}$ (assumed to behave like random oracles in the security analysis) where the security parameters satisfy $n = k + \ell$:

$$\mathcal{F} : \{0,1\}^k \to \{0,1\}^\ell \qquad \mathcal{G} : \{0,1\}^\ell \to \{0,1\}^k \qquad \mathcal{H} : \{0,1\}^k \to \{0,1\}^\ell.$$

The encryption scheme uses any probabilistic injection family $(\varphi_{\mathsf{pk}})_{\mathsf{pk}}$, whose inverses are respectively denoted ψ_{sk}, where sk is the private key associated to the public key pk. The symbol "$\|$" denotes the bit-string concatenation and identifies $\{0,1\}^k \times \{0,1\}^\ell$ to $\{0,1\}^n$.

Encryption Algorithm. The space of the plaintexts is $\mathcal{M} = \{0,1\}^\ell$, the encryption algorithm uses random coins, from two distinct sets $r \in \mathcal{R} = \{0,1\}^k$ and $\rho \in \mathrm{R}$, and outputs a ciphertext c into F: on a plaintext $m \in \mathcal{M}$, one computes

$$s = m \oplus \mathcal{F}(r) \qquad t = r \oplus \mathcal{G}(s) \qquad u = s \oplus \mathcal{H}(t) \qquad c = \varphi_{\mathsf{pk}}(t\|u, \rho).$$

Decryption Algorithm. On a ciphertext c, one first computes $t\|u = \psi_{\mathsf{sk}}(c)$, where $t \in \{0,1\}^k$ and $u \in \{0,1\}^\ell$, and then

$$s = u \oplus \mathcal{H}(t) \qquad r = t \oplus \mathcal{G}(s) \qquad m = s \oplus \mathcal{F}(r).$$

4 Security Result

In this section, we state and prove the security of this construction. A sketch is provided in the body of the paper, the full proof can be found in the full version [22].

Theorem 4. *Let $\mathcal{A}$ be an* IND-RCCA *adversary against the OAEP 3-round construction with any trapdoor one-way probabilistic function family $(\varphi_{\mathsf{pk}})_{\mathsf{pk}}$, within time τ. Let us assume that after q_f, q_g, q_h and q_d queries to the random oracles $\mathcal{F}$, $\mathcal{G}$ and $\mathcal{H}$, and the decryption oracle respectively, its advantage $\mathsf{Adv}^{\mathsf{ind\text{-}rcca}}_{\mathsf{oaep\text{-}3}}(\tau)$ is greater than ε. Then, $\mathsf{Succ}^{\mathsf{gap}}_{\varphi}(\tau', q_d(q_g q_h + q_d))$ is upper-bounded by*

$$\frac{\varepsilon}{2} - q_d^2 \times \left(\frac{1}{2^\ell} + \frac{6}{2^k}\right) - (4q_d + 1) \times \left(\frac{q_g}{2^\ell} + \frac{q_f}{2^k}\right) - q_d \times \frac{q_f + 1}{2^k},$$

with $\tau' \leq \tau + (q_f + q_g + q_h + q_d)T_{lu} + q_d^2 T_{\mathsf{Same}} + (q_d + 1)q_g q_h (T_\varphi + T_{\mathsf{Same}})$, where T_φ is the time complexity for evaluating any function φ_{pk}, T_{Same} is the time for the decisional oracle $\mathsf{Same}_{\varphi_{\mathsf{pk}}}$ to give its answer, and T_{lu} is the time complexity for a look up in a list.

4.1 Trapdoor Permutations

Before proving this general result, let us consider the particular case where φ_{pk} is a permutation from E onto F (*i.e.*, a deterministic function.) The general result has indeed several drawbacks:

- the reduction cost introduces a cubic factor $q_d q_g q_h$ which implies larger keys for achieving a similar security level as for some other constructions;
- the security relies on a gap problem, which is a strong assumption in many cases;
- and we cannot achieve the usual IND-CCA security level.

These drawbacks are acceptable as the price of generality: this becomes one of the best padding for ElGamal or Paillier strongly secure variants. However,

for trapdoor permutations, such as RSA, several OAEP variants achieve much better efficiency.

But one should interpret the above result in this particular case: first, the gap-problem becomes the classical one-wayness, since the decisional oracle is simply the equality test; Furthermore, the RCCA scenario becomes the classical CCA one; Finally, because of the determinism of the permutation, with proper bookkeeping, one can avoid the cubic factor, and fall back to the usual quadratic factor $q_g q_h$, as for any OAEP-like constructions (OAEP+, SAEP and SAEP+). Then, one can claim a much better security result:

Theorem 5. *Let $\mathcal{A}$ be an* IND-CCA *adversary against the OAEP 3-round construction with a trapdoor one-way permutation family $(\varphi_{\mathsf{pk}})_{\mathsf{pk}}$, within time τ. Let us assume that after q_f, q_g, q_h and q_d queries to the random oracles $\mathcal{F}$, $\mathcal{G}$ and $\mathcal{H}$, and the decryption oracle respectively, its advantage $\mathsf{Adv}^{\mathsf{ind\text{-}cca}}_{\mathsf{oaep\text{-}3}}(\tau)$ is greater than ε. Then, $\mathsf{Succ}^{\mathsf{ow}}_{\varphi}(\tau')$ is upper-bounded by*

$$\frac{\varepsilon}{2} - q_d^2 \times \left(\frac{1}{2^\ell} + \frac{6}{2^k}\right) - (4q_d + 1) \times \left(\frac{q_g}{2^\ell} + \frac{q_f}{2^k}\right) - q_d \times \frac{q_f + 1}{2^k},$$

with $\tau' \leq \tau + (q_f + q_g + q_h + q_d)T_{lu} + q_g q_h T_\varphi$, where T_φ is the time complexity for evaluating any function φ_{pk} and T_{lu} is the time complexity for a look up in a list.

4.2 Sketch of the Proof

The proof is very similar to the one in [21], but the larger class (injective probabilistic functions), and the improved security result (relative to the one-wayness) make some points more intricate: for a permutation f, each value x maps to a unique image $y = f(x)$; whereas for a function f, each value x maps to several images $y = f(x, \rho)$, according to the random string ρ. Consequently, when used as an asymmetric encryption primitive, the adversary may have the ability to build another y' whose pre-image is identical to the one of y: $x = g(y) = g(y')$. Such a query to the decryption oracle is not excluded in the CCA scenario, while we may not be able to either detect or answer. Hence the relaxed version of chosen-ciphertext security, and the decisional oracle Same_f: the latter helps to detect ciphertexts with identical pre-images, the relaxed scenario gives the ability to answer test in this case. Granted the decisional oracle Same_f, we can also detect whether a decryption query c has the same pre-image as a previous decryption query c' in which case we output the same plaintext. If it is a really new ciphertext, by using again the decisional oracle Same_f, we can check whether s and t have both been asked to $\mathcal{G}$ and $\mathcal{H}$, respectively, which immediately leads to the plaintext m. In the negative case, a random plaintext can be safely returned.

4.3 More Details

The full proof can be found in the full version [22], but here are the main steps, since the proof goes by successive games in order to show that the above decryp-

tion simulation is almost indistinguishable for the adversary. Then, a successful IND-RCCA adversary can be easily used for inverting the one-way function.

$\mathbf{G}_0$: We first start from the real IND-RCCA attack game.

$\mathbf{G}_1$–$\mathbf{G}_2$: We then simulate the view of the adversary, first, as usual with lists for the random oracles and the decryption oracle (see figures 1 and 2.) We then modify the generation of the challenge ciphertext, using a random mask $f^\star$, totally independent of the view of the adversary: the advantage of any adversary is then clearly zero. The plaintext is indeed unconditionally hidden.

The only way for any adversary to detect this simulation is to ask $\mathcal{F}(r^\star)$ and then detect that the answer differs from any possible $f^\star$. We are thus interested in this event, termed AskF, which denotes the event that $r^\star$ is asked to $\mathcal{F}$.

The main difference with the OAEP 2-round construction, as shown by Shoup with his counter-example [28], is that here an adversary cannot make another ciphertext with the same r as $r^\star$, in the challenge ciphertext, but either by chance, or if it had asked for *both* $\mathcal{G}(s^\star)$ and $\mathcal{H}(t^\star)$. We now try to show this fact.

$\mathbf{G}_3$–$\mathbf{G}_8$: We thus modify the decryption process so that it makes no new query to $\mathcal{G}$ and $\mathcal{H}$. The sequence of games leads to the following new rules:

▶**Rule** Decrypt-noT$^{(8)}$

> Choose $m \stackrel{R}{\leftarrow} \{0,1\}^\ell$.

▶**Rule** Decrypt-TnoS$^{(8)}$

> Choose $m \stackrel{R}{\leftarrow} \{0,1\}^\ell$.

▶**Rule** Decrypt-TSnoR$^{(8)}$

> If $s = s^\star$ but $s^\star$ has not been directly asked by the adversary yet: $m \stackrel{R}{\leftarrow} \{0,1\}^\ell$.
> Else, one chooses $m \stackrel{R}{\leftarrow} \{0,1\}^\ell$, computes $f = m \oplus s$ and adds (r, f) in $\mathcal{F}$-List.

▶**Rule** EvalGAdd$^{(8)}$

> For each $(t, h) \in \mathcal{H}$-List and each $(m, c) \in \mathcal{D}$-List, choose an arbitrary random $\rho \in \mathrm{R}$ and ask for $(c, c' = \varphi_{\mathsf{pk}}(t \| h \oplus s, \rho))$ to the decisional oracle $\mathsf{Same}_{\varphi_{\mathsf{pk}}}$. If the record is found (the decisional oracle $\mathsf{Same}_{\varphi_{\mathsf{pk}}}$ answers "yes"), we compute $r = t \oplus g$ and $f = m \oplus s$, and finally add (r, f) in $\mathcal{F}$-List.

Some bad cases may appear, which make our simulation to fail. But they are very unlikely, we thus can safely cancel executions, applying the following rule

$\mathcal{F}$, $\mathcal{G}$ and $\mathcal{H}$ Oracles

Query $\mathcal{F}(r)$: if a record (r, f) appears in $\mathcal{F}$-List, the answer is f.
Otherwise the answer f is chosen randomly in $\{0,1\}^k$ and the record (r, f) is added in $\mathcal{F}$-List.

Query $\mathcal{G}(s)$: if a record (s, g) appears in $\mathcal{G}$-List, the answer is g.
Otherwise the answer g is chosen randomly in $\{0,1\}^\ell$ and the record (s, g) is added in $\mathcal{G}$-List.

▶**Rule** EvalGAdd$^{(1)}$

| Do nothing `% To be defined later`

Query $\mathcal{H}(t)$: if a record (t, h) appears in $\mathcal{H}$-List, the answer is h.
Otherwise the answer h is chosen randomly in $\{0,1\}^k$ and the record (t, h) is added in $\mathcal{H}$-List.

$\mathcal{D}$ Oracle

Query $\mathcal{D}_{\mathsf{sk}}(c)$: first, if we are in the second stage (the challenge $c^\star$ as been defined), ask for $(c, c^\star)$ to the decisional oracle $\mathsf{Same}_{\varphi_{\mathsf{pk}}}$. In case of positive decision, the answer is test.
Else, for each (m', c') in $\mathcal{D}$-List, ask for (c, c') to the decisional oracle $\mathsf{Same}_{\varphi_{\mathsf{pk}}}$. In case of a positive decision, the answer is the corresponding'm'.
Otherwise, the answer m is defined according to the following rules:

▶**Rule** Decrypt-Init$^{(1)}$

| Compute $t \| u = \psi_{\mathsf{sk}}(c)$;

Look up for $(t, h) \in \mathcal{H}$-List:

- if the record is found, compute $s = u \oplus h$.
  Look up for $(s, g) \in \mathcal{G}$-List:
  - if the record is found, compute $r = t \oplus g$.
    Look up for $(r, f) \in \mathcal{F}$-List:
    - if the record is found
      ▶**Rule** Decrypt-TSR$^{(1)}$
      | $h = \mathcal{H}(t)$,
      | $s = u \oplus h, \quad g = \mathcal{G}(s)$,
      | $r = t \oplus g, \quad f = \mathcal{F}(r)$,
      | $m = s \oplus f$.
    - else
      ▶**Rule** Decrypt-TSnoR$^{(1)}$
      | same as rule Decrypt-TSR$^{(1)}$.
  - else
    ▶**Rule** Decrypt-TnoS$^{(1)}$
    | same as rule Decrypt-TSR$^{(1)}$.
- else
  ▶**Rule** Decrypt-noT$^{(1)}$
  | same as rule Decrypt-TSR$^{(1)}$.

Answer m and add (m, c) to $\mathcal{D}$-List.

Fig. 1. Formal Simulation of the IND-RCCA Game: Oracles

Challenger

For two messages (m_0, m_1), flip a coin b and set $m^\star = m_b$, choose randomly $r^\star$ then answer $c^\star$ where

►**Rule** $\mathsf{Chal}^{(1)}$

$f^\star = \mathcal{F}(r^\star), \quad s^\star = m^\star \oplus f^\star,$
$g^\star = \mathcal{G}(s^\star), \quad t^\star = r^\star \oplus g^\star,$
$h^\star = \mathcal{H}(t^\star), \quad u^\star = s^\star \oplus h^\star.$

►**Rule** $\mathsf{ChalC}^{(1)}$

and $c^\star = \varphi_{\mathsf{pk}}(t^\star \| u^\star, \rho^\star)$, for random string $\rho^\star$.

Fig. 2. Formal Simulation of the IND-RCCA Game: Challenger

►**Rule** $\mathsf{Abort}^{(1)}$

Abort and output a random bit:

- If $s^\star$ has been asked to $\mathcal{G}$ by the adversary, while the latter did not ask for $\mathcal{H}(t^\star)$.
- If a Decrypt-TSR/Decrypt-TSnoR rule has been applied with $t = t^\star$, while $\mathcal{H}(t^\star)$ had not been asked by the adversary yet.
- If a Decrypt-TSR rule has been applied with $s = s^\star$, while $\mathcal{G}(s^\star)$ had not been asked by the adversary yet.

The remaining bad case (termed AskGHA) is if both $s^\star$ and $t^\star$ have been asked to $\mathcal{G}$ and $\mathcal{H}$ by the adversary. Such a case helps the adversary to distinguish our simulation. On the other hand, this case helps to invert φ_{pk}.

G$_9$: With these new rules for decryption, the simulation of the decryption oracle does not use at all the queries previously asked to $\mathcal{G}$ and $\mathcal{H}$ by the generation of the challenge, but just the queries directly asked by the adversary, which are available to the simulator (we remind that we are in the random-oracle model.) One can thus make $g^\star$ and $h^\star$ to be values independent to the view of the adversary:

►**Rule** $\mathsf{Chal}^{(9)}$

The two values $r^+ \xleftarrow{R} \{0,1\}^k$ and $f^+ \xleftarrow{R} \{0,1\}^\ell$ are given, as well as $g^+ \xleftarrow{R} \{0,1\}^k$ and $h^+ \xleftarrow{R} \{0,1\}^\ell$ then $r^\star = r^+$, $f^\star = f^+$, $s^\star = m^\star \oplus f^+$, $g^\star = g^+$, $t^\star = r^+ \oplus g^\star$, $h^\star = h^+$ and $u^\star = s^\star \oplus h^\star$.

And then the decryption oracle can be simply replaced by the classical plaintext-extractor which looks up in the lists $\mathcal{G}$-List and $\mathcal{H}$-List (which only contain the queries directly asked by the adversary) to obtain the values (s, g) and (t, h) which match with $c = \varphi_{\mathsf{pk}}(t \| s \oplus h, \rho)$, using the decisional oracle $\mathsf{Same}_{\varphi_{\mathsf{pk}}}$, but without using anymore ψ_{sk}. In case of failure, one answers a random plaintext m.

> We simply conclude, since our reduction does not use any oracle, but can answer any query of the adversary, in an indistinguishable way, unless the bad case AskGHA happens: in which case we have inverted φ_{sk}.

The time complexity of one simulation is thus upper-bounded by $q_g q_h \times (T_\varphi + T_{\mathsf{Same}})$, where T_φ is the time to evaluate one function in the φ family, and T_{Same} the time for the decisional oracle, plus the initial look up in the $\mathcal{D}$-List: $T_{lu} + q_d T_{\mathsf{Same}}$. Thus the global running time is bounded by (including all the list look up):

$$\tau' \leq \tau + q_d q_g q_h \times (T_\varphi + T_{\mathsf{Same}}) + q_d^2 \times T_{\mathsf{Same}} + (q_f + q_g + q_h + q_d) \times T_{lu}.$$

In the particular case where φ_{pk} is a permutation from E onto F (a deterministic one), one can improve it, using an extra list of size $q_g q_h$, which stores all the tuples $(s, g = \mathcal{G}(s), t, h = \mathcal{H}(t), c' = \varphi_{\mathsf{pk}}(t \| s \oplus h))$. The time complexity then falls down to $\tau + q_g q_h \times T_\varphi + (q_f + q_g + q_h + q_d) \times T_{lu}$.

5 Conclusion

All the OAEP variants [28, 6] applied to RSA, with general exponents (*i.e.*, not Rabin nor $e = 3$) admit, in the best cases, reductions to the RSA problem with a quadratic loss in time complexity [24] – the original OAEP is even worst because of the reduction to the partial-domain case, which requires a more time consuming reduction to the full-domain RSA problem. Furthermore, for a security level in 2^{-k}, a randomness of $2k$ bits is required, plus a redundancy of k bits.

In this paper, we show that the variant of OAEP with 3 rounds admits a reduction as efficient as the best OAEP variants (to the full-domain RSA, when applied to the RSA family) without having to add redundancy: one can thus earn k bits. But this is not the main advantage.

Considering any criteria, OAEP with 3 rounds is at least as good as all the other OAEP variants, but from a more practical point of view

- since no redundancy is required, implementation becomes easier, namely for the decryption process [16];
- it applies to more general families than just (partial-domain) one-way trapdoor permutations, but to any probabilistic trapdoor one-way function. It is thus safer to use it with a new primitive [15].

As a conclusion, OAEP with 3 round is definitely the most generic and the simplest padding to use with almost all the encryption primitives.
