#### Abstract

Previous work on voter control, which refers to situations where a chair seeks to change the outcome of an election by deleting, adding, or partitioning voters, takes for granted that the chair knows all the voters' preferences and that all votes are cast simultaneously. However, elections are often held sequentially and the chair thus knows only the previously cast votes and not the future ones, yet needs to decide instantaneously which control action to take. We introduce a framework that models online voter control in sequential elections. We show that the related problems can be much harder than in the standard (non-online) case: For certain election systems, even with efficient winner problems, online control by deleting, adding, or partitioning voters is PSPACE-complete, even if there are only two candidates. In addition, we obtain (by a new characterization of coNP in terms of weight-bounded alternating Turing machines) completeness for coNP in the deleting/adding cases with a bounded deletion/addition limit, and we obtain completeness for NP in the partition cases with an additional restriction. We also show that for plurality, online control by deleting or adding voters is in P , and for partitioning voters is coNP-hard.

[^0]
## 1 Introduction

Elections are important not just in the human world. They also can function as an important way of aggregating the preferences of (often electronic) agents, in our world that is increasingly networked and in which people and institutions will increasingly be spoken for by automated agents.

In the field of multiagent systems, voting has been suggested for tasks as varied as, for example, recommender systems, collaborative spam filtering, and planning [ER97, GMHS99, DKNS01]. And not surprisingly, the study of the computational properties of voting systems has been an exceedingly active area within computational social choice.

In particular, various types of manipulation, electoral control, and bribery in voting have been classified in terms of their computational complexity (see [FHHR09b, FHH10]). This paper focuses on voter control, a model introduced by Bartholdi, Tovey, and Trick [BTT92], where a chair attempts to alter the outcome of an election via changing its structure by deleting, adding, or partition of voters. These types of control seek to model such real-world behaviors as targeted vote suppression, bring-out-the-vote drives, and districting/gerrymandering. Bartholdi, Tovey, and Trick's paper was in the bounded-rationality spirit of Simon [Sim69], and was in part making the point that computational complexity is important in decision-making.

There have been many papers analyzing the (non-online) control complexity of election systems, and seeking to find natural systems that make many types of control attack difficult (see the surveys [FHHR09b, FHH10], the book chapters [BR16, FR16, HHR16], and the references therein). To the best of our knowledge, all previous work on control (see, e.g., [BTT92, HHR07, FHHR09a, HHR09, ENR09, EFRS15]) takes for granted that the chair has full knowledge of all the voters' preferences and that all votes are cast simultaneously 1 . However, in many settings voters vote sequentially and the chair's task in such a setting may often be quite different: Knowing only the already cast votes but not the future ones, the chair must decide online (i.e., in that moment) whether there exists a control action that guarantees success, no matter what votes will be cast later on. We introduce a framework to model online voter control in sequential elections. Our approach is inspired by the area of "online algorithms" [BE98]-algorithms running and performing computational actions based only on the input data seen thus far.

In our framework of online voter control, the chair's task stated above is based on a "maxi-min" idea (although here, due to the time effects, that can involve more than two quantifiers), a typical online-algorithmic theme; in that framing of the chair's task we are following the approach that has been used for online manipulation and online candidate control [HHR14 HHR12a]. Note that another central online-algorithmic theme, a strictly numerical ratio approach to so-called "competitive analysis," would not apply very naturally here; the reason is that in its general setting, voting (in social-choice theory) is most typically based on an ordinal notion of preferences, and those don't convey cardinal strength-of-affinity information regarding the outcome. (For some specific voting systems such as so-called scoring systems one can interpret them as giving cardinal information, and we commend as an interesting open issue a future, general control-complexity study for such sys-

[^1]tems in terms of a competitive-ratio analysis; see [OL14], which takes that approach for the issue of selecting a bundle of goods.) Sequential (or otherwise "dynamic") voting has been studied in other contexts as well, e.g., from a game-theoretic perspective as "Stackelberg voting games" XC10] (see also [DE10, DP01, Slo93]), or using an axiomatic approach [Ten04] or Markov decision processes [PP13]. None of this work has considered the issue of voter control.

What our results show is that such online control problems can be much harder than in the standard (non-online) case. We show that for certain election systems, even with efficient winner problems, online control by deleting, adding, or partitioning voters is PSPACE-complete, even if there are only two candidates. In addition, we obtain completeness for coNP in the deleting/adding cases with a bounded deletion/addition limit. We do this by establishing a complexity-theoretic result (Theorem4.3) that is of interest in its own right: Polynomial-time alternating Turing machines that on each accepting path make a constant number of "Yes" guesses accept only coNP languages, and in fact this completely characterizes coNP. We also show that for plurality, online control by deleting or adding voters is in P , and for partitioning voters is coNP-hard.

## 2 Motivation

The coming sections will give our definitions, results, and proofs. However, before that, the present section will very informally present some motivation and examples. In particular, we give example settings in which it is natural to study sequential action, in which the election's "chair" has a use-it-or-lose-it ability to do addition/deletion/partition-choice for each voter as the voter votes, and the chair knows the votes of the voters seen so far, but not of future voters. Of course, theoretical models don't capture the many interactions and subtleties of the real world, and so our models don't perfectly capture the full richness of even these sample situations. Nonetheless, we feel that for many cases, such as those we are about to mention, the theoretical models we develop in this paper are far closer to capturing the real-world situation than are existing models of simultaneous voting or even existing models where votes are sequential but all voters' preferences are known ahead of time.

As a concrete example (and let us for the moment not worry about what the particular election system is), consider a College faculty meeting at which, going right around the room, the faculty members hand their handwritten paper ballots to the Dean, who then passes them on to her administrative assistant, who quietly adds them to the totals he is keeping. But let us further assume that the Dean is a shifty person, and can, for a certain number of ballots, slip the piece of paper into her pocket after reading the vote, without that being noticed, and without the people in the room being likely to notice that there aren't quite enough votes in the totals (let's suppose it is a big college). And the question is, given that we are at some particular point in going around the table (and know what votes have been cast so far and what actions the Dean-or whoever was standing in for her-has taken so far): Can the Dean ensure, using at most her remaining amount of vote-to-pocket shifting, that the winner(s) of the election will include at least one of the alternatives she favors? This setting loosely corresponds to our sequential version of control by deleting voters. For vividness, our examples are about humans voting and a human chair (in the above, the Dean), and in the case just given, paper ballots. However, our model applies also to more electronically focused
cases of preference aggregation, e.g., the "Dean" in the above example could be a doctored voting machine that can only suppress so many ballots before seriously risking detection.

The above example is about deleting voters, but there are also natural examples for adding or partitioning voters. For partitioning voters, imagine that a school's undergraduate admissions office is going to use a panel, whose members will each be assigned to one of two faculty committees, to vet applying students (perhaps with the committees purportedly looking for different things, e.g., one is looking for traditional smartness and the other is looking for unusual levels of passion and creativity), with all applicants' folders given to both committees, and with each committee using voting to select its favorite proposals, and then with only the winners of those two vetting elections moving on to a final election in which all the panel members vote. Suppose a particular admissions office staff member (who is the chair in this example), with all the faculty members lined up and coming into the room, as each faculty member steps to the doorway briefly chats with the faculty member well enough to discern the likely votes he or she will cast, and then right there assigns the person to either the smartness committee or the passion committee. If the admissions staff member does so with the goal of ensuring that at least one of a certain set of students (perhaps the students who are great football quarterbacks, or the students whose parents might fund a new admissions building) will be admitted, that very loosely put would be captured by our sequential version of control by partition of voters. 2 For adding voters, a natural model might be a political candidate (who is the chair in this example) going door to door through her district in a preset order, and knowing from public records which voters are registered voters and which are not, and at each door meeting and learning the voter's preferences among the candidates, and then for those voters who are not registered deciding whether to use charisma to convince them to register and vote, with the limitation that the candidate has only so much charisma to use.

The above are a few very informal examples of settings where sequential action is natural, and one knows the votes cast so far but not those to be cast in the future (except who will be casting them and in which order). Let us finish this informal section by briefly giving a mini-example of the flavor of the goal we have for our chairs, and how that affects their actions. We are assuming that chairs are very pessimistic: What a chair wants to know is whether there is some action she can take at the given moment so that one of her preferred candidates will win no matter what the value is of all the currently unknown-to-her future votes-but assuming that her own future decisions are (of course) aimed at supporting her goal. To make this more concrete, let us discuss the most important realworld election system: plurality. In our addition-of-voters example above, suppose the candidate going door to door has only one preferred candidate in the election, namely, herself. Then it is quite clear and simple what she should do. Until she runs out of charisma, she should for each unregistered voter she meets for whom she is the favorite candidate expend her charisma to have that person become a registered voter. That is an "operational" approach that would work perfectly. But more must be said. The question our pessimistic candidate (and our decision problems) wants answered at each point is whether, whatever the preferences still to come after the current point are, that candidate will win. And it is also clear how to judge that. The candidate, as she starts speaking

[^2]with a given unregistered voter who likes our candidate the most (we can similarly describe how to reason in the other cases), reasons as follows: I need to assume that all future voters (whose preferences I don't currently know!) concentrate their votes on a candidate other than me who currently has the most votes (in the tally I have been building in my canvas so far), and that I use my charisma to (if it is not expended) add the current unregistered voter, and then I suppress those hypothetical, unregistered, against-me voters, and would that leave me a winner of this election? If the answer is yes, then the candidate should be very happy, as she knows she can guarantee herself victory as long as she doesn't later do anything overtly stupid with her charisma. The example we just gave is in effect explaining why it holds that (so-called constructive) control by adding voters is in polynomial time for sequential plurality elections. Now, one might assume that plurality is such a simple system that for all types of sequential control we will obtain polynomial-time algorithms. However, as Theorem 5.2 we will show that that is not the case (unless $\mathrm{P}=\mathrm{NP}$ ). The proof of that result is in effect giving an example-although admittedly a more complex one-in which a coNP-hard problem, namely the complement of Hitting Set, is transformed into an election control instance about sequentially partitioning voters (the control setting we described above in our example about college admissions).

## 3 Preliminaries

We assume familiarity with standard complexity-theoretic notions such as the complexity classes P , NP, coNP, and PSPACE, polynomial-time many-one reductions $\left(\leq_{m}^{p}\right), \leq_{m}^{p}$-hardness, and $\leq_{m}^{p}{ }^{-}$ completeness [HU79, Pap94]. A standard NP-complete problem is the satisfiability problem (SAT) from propositional logic, a standard coNP-complete problem is the tautology problem, and the quantified boolean formula problem (QBF) is a standard PSPACE-complete problem.

This paper provides both polynomial-time algorithms and NP-completeness results. The latter are worst-case results, and so it is possible that for certain distributions heuristics might do well (see [RS13] for a survey of this in the context of elections). We commend this direction as an area for future research. However, such studies are quite dependent on distributions, and by relatively recent work, it is known that for the uniform distribution heuristic algorithms cannot asymptotically have subexponential error frequency on any NP-hard problem unless the polynomial hierarchy collapses to (and indeed, slightly further than) its third level [BH08, CCHO05, HW12]. (Note: An algorithm is said to have subexponential error frequency if for every $\varepsilon>0$ the number of errors the algorithm makes at length $n$ is $O\left(2^{n^{\varepsilon}}\right)$; see HW12] for a more detailed explanation.)

### 3.1 Voter Control Types in Simultaneous Elections

A pair $(C, V)$ is called a (standard or simultaneous) election if $C$ is a set of candidates and $V$ a list of voters that all have cast their votes simultaneously. We assume that each vote in $V$ has the form $(v, p)$, where $v$ is the name of this voter and $p$ is $v$ 's (total) preference order over $C$. For example, if $C=\{c, d, e\}$ then (Bob, $d>e>c) \in V$ indicates that Bob (strictly) prefers $d$ to $e$ and $e$ to $c$ (or, to be more precise, it indicates that that is the ballot Bob has cast).

The standard types of (constructive) voter control in simultaneous elections are as follows.
(These are as introduced by Bartholdi, Tovey, and Trick [BTT92], except here we will follow the now more standard model-called the nonunique-winner model-of asking whether a candidate can be made $a$ winner, rather than their approach-called the unique-winner model-of asking whether a candidate can be made the one and only winner.) An election system is a mapping from elections (votes/candidates) to a winner set. Let $\mathscr{E}$ be a given election system. In control by deleting voters ( $\mathscr{E}$-CCDV), given an election $(C, V)$, a distinguished candidate $c \in C$, and a nonnegative integer $k \leq\|V\|$, we ask whether there exists a set of at most $k$ voters from $V$ such that $c$ is an $\mathscr{E}$ winner of the election in which that set of voters is removed. In control by adding voters ( $\mathscr{E}$-CCAV), we are given a candidate set $C$, a list $V$ of registered voters with preferences over $C$, a list $V^{\prime}$ of as yet unregistered voters with preferences over $C$, a distinguished candidate $c \in C$, and a nonnegative integer $k \leq\left\|V^{\prime}\right\|$, and the question is whether there exists a set of at most $k$ voters from $V^{\prime}$ such that $c$ is an $\mathscr{E}$ winner of the election where the voters are that set and all of $V$. Finally, in control by partition of voters, we are given an election $(C, V)$ and a distinguished candidate $c \in C$, and we ask whether $V$ can be partitioned into two sublists, $V_{1}$ and $V_{2}$, such that $c$ is an $\mathscr{E}$ winner of the election ( $W_{1} \cup W_{2}, V$ ), where $W_{i}$ for $i \in\{1,2\}$ is the (possibly empty) set of winners of subelection $\left(C, V_{i}\right)$ that have survived the tie-handling rule used and by $V$ here we implicitly mean $V$ masked down to just those candidates in $W_{1} \cup W_{2}$. Of the two tie-handling models introduced by Hemaspaandra, Hemaspaandra, and Rothe HHR07] we focus on the ties-promote (TP) model only, where all winners of a subelection proceed to the runoff, since that model fits more naturally with the nonunique-winner model in which we will define our online control problems. The resulting problem is denoted by $\mathscr{E}$-CCPV.

The destructive variants of these three problems, denoted by $\mathscr{E}$-DCDV, $\mathscr{E}$-DCAV, and $\mathscr{E}$-DCPV, are obtained by requiring that the distinguished candidate $c$ is not a winner of the election resulting from the control action at hand [HHR07].

### 3.2 Online Voter Control in Sequential Elections

We study online voter control in sequential elections, where we assume that the voters vote in order, one after the other, each expressing preferences over all the candidates. If $u$ is the current voter and $C$ the given candidate set, an election snapshot for $C$ and $u$ is specified by a triple $V=\left(V_{<u}, u, V_{u<}\right)$, where the earlier voters $V_{<u}$ have already cast their votes, each a preference order over $C$, and now it is $u$ 's turn to cast a vote, and the future voters $V_{u<}$ will cast their votes in the order listed. ( $V_{<u}$ and $u$ of course list the votes cast and who cast them, but $V_{u<}$ just gives the order of the voters following $u$.) This snapshot approach is natural for studying online attacks on elections, and was used previously to study the different type of attack known as online manipulation in sequential elections [HHR13, HHR14].

We now define our notions of online voter control for the standard voter control types stated above, and the related problems. They all will start from a basic online voter control setting (an OVCS, for short), augmented by appropriate additional information according to the control type at hand. A basic OVCS $(C, u, V, \sigma, d)$ consists of a set $C$ of candidates, the current voter $u$ (which isn't strictly needed here, as $u$ is clearly singled out within $V$ anyway), an election snapshot $V$ for $C$ and $u$, the chair's preference order $\sigma$ on $C$, and a distinguished candidate $d \in C$. Let $\mathscr{E}$ be a given election system and let $W_{\mathscr{E}}(C, V)$ denote the $\mathscr{E}$ winner set of (standard) election ( $C, V$ ). For
each online voter control type we will define, the question the chair faces is: Does there exist a control-action choice of our considered type regarding the current voter (e.g., whether or not to delete $u$ ) such that if the chair takes that action, then no matter what votes the remaining voters after $u$ cast, the chair's goal can be reached by the current decision regarding $u$ and by using the chair's future decisions (if any), each being made using the chair's then-in-hand knowledge about what votes have been cast by then $\sqrt[3]{3}$ By the chair's goal we mean to ensure $W_{\mathscr{E}}\left(C, V^{\prime}\right) \cap\left\{c \mid c \geq_{\sigma} d\right\} \neq \emptyset$ for each possible ultimate election ( $C, V^{\prime}$ ) (i.e., each $V^{\prime}$ is a possible vote list resulting from the control type at hand after all decisions have been made by the chair and all voters have cast their votes) in the constructive case, and to ensure that $W_{\mathscr{E}}\left(C, V^{\prime}\right) \cap\left\{c \mid d \geq_{\sigma} c\right\}=\emptyset$ in the destructive case (i.e., that neither $d$ nor any candidate the chair likes even less than $d$ is a winner) ${ }_{4}^{4}$ Note that the conditions $W_{\mathscr{E}}\left(C, V^{\prime}\right) \cap\left\{c \mid c \geq_{\sigma} d\right\} \neq \emptyset$ and $W_{\mathscr{E}}\left(C, V^{\prime}\right) \cap\left\{c \mid d \geq_{\sigma} c\right\}=\emptyset$ defining the chair's goal have the flavor, give or take the fact that we are focusing on a top segment of $\sigma$, of the nonuniquewinner model, e.g., as long as $W_{\mathscr{E}}\left(C, V^{\prime}\right) \cap\left\{c \mid c \geq_{\sigma} d\right\} \neq \emptyset$ we call it success even if more than one candidate ties as winner. To formally define our problems, it remains to specify for each control type the information by which the basic OVCS is augmented. What kind of decisions the chair is to make in the course of a sequential election will always be clear from the control type at hand (e.g., whether or not to delete a voter in "online control by deleting voters").

Let $B=(C, u, V, \sigma, d)$ be a given basic OVCS. For online control by deleting voters, $B$ is augmented by the following additional information: A nonnegative integer $k$ (the deletion upper bound); for each voter $v$ before $u$, there is a flag saying whether $v$ was deleted and the vote cast by $v$ (if not deleted)—at most $k$ voters can be marked as deleted for the input to be syntactically legal; and

[^3]the vote the current voter $u$ will cast (if not selected for deletion). We denote these problems by online- $\mathscr{E}$-CCDV (constructive) and online- $\mathscr{E}$-DCDV (destructive). (We certainly could equivalently formulate the problem in a way that masks out all earlier deleted voters, and so removes the need for the flagging; but we prefer the above version since it allows the actual history of the voting situation to be part of the instance.)

For online control by adding voters, $B$ is augmented by the following additional information: A nonnegative integer $k$ (the addition upper bound); each voter $v$ in $V$ has a flag saying if $v$ is unregistered (i.e., can be added) or registered- $u$ must be unregistered; each unregistered voter $v$ before $u$ has another flag saying if $v$ was added-at most $k$ voters may have that flag set in any syntactically legal input; the vote cast is given for each registered or added unregistered voter before $u$; and also given is the vote $u$ will cast (if it is added). We denote these problems by online- $\mathscr{E}$-CCAV (constructive) and online- $\mathscr{E}$-DCAV (destructive).

For online control by partition of voters, $B$ is augmented by the following additional information: Each voter $v$ before $u$ has a flag saying which part of the partition $v$ was assigned to ("left" or "right") and the vote cast by $v$, and also $u$ 's vote is given. We denote these problems by online- $\mathscr{E}$-CCPV (constructive) and online- $\mathscr{E}$-DCPV (destructive). As a reminder, the two preliminary elections are conducted under the convention that "ties promote" (i.e., all winners of the preliminary elections move forward to the final election).

A natural worry about our maxi-min approach to online voter control is that it is always possible that all the future voters are hostile to one's goals. And in that case, one may be, depending on the election system, powerless to reach one's goal in the worst case, and so the maxi-min outcome is easily seen to be failure to reach one's goal. Although this worry exists in a weaker form for online manipulation and online bribery, since for those if one is allowed almost no vote-changing one is in many cases obviously in trouble, at least in those settings one can do whatever one wants to those votes one does manipulate or bribe. In control, however, one doesn't get to set the value of a single vote, and that is pretty extreme.

This is a valid worry, but there are some things that keep it in perspective. Primarily, our paper is trying to find out the very greatest complexity that online control in sequential elections can ever have (when restricted to election systems having polynomial-time winner problems). And so we can look at election systems that sidestep the above worry, due to their properties simply not matching the intuition above (which assumed that we are using an election system in which having a lot of bad-for-us votes results in a bad-for-us outcome). In effect, we are seeking to understand the limits of behavior, in order to set a bounding box on the behaviors that can be realized. Of course, for many natural election systems, the effect mentioned in the previous paragraph will hold, and for many inputs that fact can be exploited to help achieve polynomial-time algorithms for the control problem; indeed, in this paper itself, we give examples of achieving polynomial-time algorithms for the most important of election systems: plurality. Of course, problems may start with some votes already cast, and this may itself make for interesting "endgame" decision issues. We also very much hope further studies will be conducted employing a range of models, including ones beyond maxi-min.

## 4 General Upper and Lower Bounds

Theorem 4.1 For each election system $\mathscr{E}$ with a polynomial-time winner problem, 5 online- $\mathscr{E}$-CCDV, online- $\mathscr{E}$-DCDV, online- $\mathscr{E}$-CCAV, online- $\mathscr{E}$-DCAV, online- $\mathscr{E}-\mathrm{CCPV}$, and online- $\mathscr{E}$-DCPV are in PSPACE.

Proof. The upper bounds follow from the observation that each of these problems can be solved by an alternating Turing machine in polynomial time, and thus by a deterministic polynomial-space Turing machine, by the characterization due to Chandra, Kozen, and Stockmeyer [CKS81].

Theorem 4.1 settles all general (i.e., regarding any voting system for which winner determination is easy) upper bounds for our online voter control problems. We now turn to exploring their lower bounds.

### 4.1 Control by Deleting and by Adding Voters

Theorem 4.2 There exist election systems $\mathscr{E}$ and $\mathscr{E}^{\circ}$ with polynomial-time winner problems such that online- $\mathscr{E}$-CCDV, online- $\mathscr{E}-\mathrm{CCAV}$, online- $\mathscr{E}^{\prime}-\mathrm{DCDV}$, and online- $\mathscr{E}^{\prime}$-DCAV are PSPACEcomplete, even when limited to two candidates.

Proof. Let $(C, V)$ be an election. We define election system $\mathscr{E}$ as follows. $\mathscr{E}$ interprets-in some fixed, natural encoding-the lexicographically least candidate name in $C$ as a boolean formula, $\Phi$, whose variable names must be the strings $x_{1}, x_{2}, \ldots, x_{2 \ell}$ for some $\ell$, where $x_{2 \ell}$ actually appears in $\Phi$ (the other variables don't have to; no variables other than $x_{1}, x_{2}, \ldots, x_{2 \ell}$ are allowed). If these syntactic requirements fail to hold, everyone loses in $\mathscr{E}$. Otherwise, if any two voters in $V$ have the same name, everyone loses in $\mathscr{E}$. Otherwise, order the voters in $V$ lexicographically by name of the voter, and let $v_{1}, v_{2}, \ldots, v_{z}$ be the voter names in this order. If $z<2 \ell$ or if there are less than two candidates, everyone loses in $\mathscr{E}$. Otherwise, if for some odd $i, 1 \leq i \leq 2 \ell-1$, the two lowest order bits of $v_{i}$ are not 00 or 01 , or if for some even $i, 2 \leq i \leq 2 \ell$, the two lowest order bits of $v_{i}$ are not 10 or 11, everyone loses in $\mathscr{E}$. Otherwise, assign the variables of $\Phi\left(x_{1}, x_{2}, \ldots, x_{2 \ell}\right)$ as follows. For each odd $i, 1 \leq i \leq 2 \ell-1$, set $x_{i}$ to true if the two lowest order bits of $v_{i}$ are 01 , and set $x_{i}$ to false otherwise (i.e., the two lowest order bits of $v_{i}$ are 00 ). For each even $i, 2 \leq i \leq 2 \ell$, set $x_{i}$ to true if the name of the least preferred candidate in the vote of $v_{i}$ is lexicographically less than the name of the next to least preferred candidate in the vote of $v_{i}$, and set $x_{i}$ to false otherwise. If this assignment satisfies $\Phi$, everyone wins in $\mathscr{E}$, and otherwise everyone loses. This ends the specification of $\mathscr{E}$. Since a boolean formula whose variables have all been assigned can be evaluated in polynomial time, $\mathscr{E}$ has a polynomial-time winner problem.

By Theorem 4.1 online- $\mathscr{E}$-CCDV is in PSPACE. To show PSPACE-hardness of online- $\mathscr{E}-\mathrm{CCDV}$, we $\leq_{m}^{p}$-reduce the PSPACE-complete problem $\mathrm{QBF}^{\prime}$, a variant of QBF, to it. $\mathrm{QBF}^{\prime}$ is the set of boolean formulas of the form $F\left(x_{1}, x_{2}, \ldots, x_{2 \ell}\right)$, for some $\ell$, such that the variable $x_{2 \ell}$ appears in $F$, all variables appearing in $F$ are from the variable name collection " $x_{1}$ ", " $x_{2}$ ", $\ldots$, " $x_{2 \ell}$ ", and

$$
\left(\exists b_{1}\right)\left(\forall b_{2}\right) \cdots\left(\exists b_{2 \ell-1}\right)\left(\forall b_{2 \ell}\right)\left[F\left(x_{1}:=b_{1}, x_{2}:=b_{2}, \ldots, x_{2 \ell}:=b_{2 \ell}\right) \text { evaluates to true }\right] \text {, }
$$

[^4]where $b_{i} \in\{0,1\}$ and $x_{i}:=b_{i}$ means that variable $x_{i}$ is set to true if $b_{i}=1$, and is set to false if $b_{i}=0$, for $1 \leq i \leq 2 \ell$.

Let $F\left(x_{1}, x_{2}, \ldots, x_{2 \ell}\right)$ be a given instance of $\mathrm{QBF}^{\prime}$, where $x_{2 \ell}$ explicitly appears in $F$. (If our input is syntactically incorrect, we map it to a fixed no-instance of online- $\mathscr{E}$-CCDV.) We construct from $F$ an instance of online- $\mathscr{E}$-CCDV, consisting of a basic OVCS $(C, u, V, \sigma, d)$, augmented by the additional information of online control by deleting voters, as follows. Define $C=\{a, b\}$, where $a$ encodes $F$ (in our fixed, natural encoding of boolean formulas) and $b$ is the string lexicographically immediately following $a$; the current voter is $u=v_{1} ; V$ will be specified below; the chair's preference order is $a>_{\sigma} b$; for specificity, we let $d=a$ be the distinguished candidate (though that does not matter, as all candidates win or all lose in $\mathscr{E}$ ); the deletion limit is $k=\ell$; and a vote $a>b$ to cast for $u$ if not deleted (again, the vote doesn't matter, as $u=v_{1}$ will specify an assignment to $x_{1}$ by her name, not by her vote). There are $(3 / 2) \cdot 2 \ell=3 \ell$ voters in $V$ such that the name of the $i$ th voter, $v_{i}$, is the binary string $u_{i} w_{i}$, where $u_{i}$ is the binary representation of $i$ and $w_{i}=00$ if $i \equiv 1 \bmod 3$, $w_{i}=01$ if $i \equiv 2 \bmod 3$, and $w_{i}=10$ if $i \equiv 0 \bmod 3,1 \leq i \leq 3 \ell$. This completes the description of our $\leq_{m}^{p}$-reduction from $\mathrm{QBF}^{\prime}$ to online- $\mathscr{E}$-CCDV, which clearly can be computed in polynomial time.

We claim that $F \in \mathrm{QBF}^{\prime}$ if and only if the chair's goal can be reached by at most $k$ deletions of voters. Why? By the definition of $\mathscr{E}$, everyone loses unless our $k=\ell$ deletions are used on exactly one of $v_{3 i-2}$ and $v_{3 i-1}$, for each $i, 1 \leq i \leq \ell$. No $v_{3 i}, 1 \leq i \leq \ell$, can be deleted if there is to be a winner. And the "exactly one of $v_{3 i-2}$ and $v_{3 i-1}$ " choices, $1 \leq i \leq \ell$, specify an assignment of truth values to the odd-numbered variables: For each $i, 1 \leq i \leq \ell, x_{2 i-1}$ is set to true if $v_{3 i-2}$ is deleted and $v_{3 i-1}$ is not, and is set to false if $v_{3 i-1}$ is deleted and $v_{3 i-2}$ is not. On the other hand, for each $i, 1 \leq i \leq \ell$, the truth value of $x_{2 i}$ is specified by the vote of voter $v_{3 i}$, since after these $\ell$ deletions, $v_{3 i}$ will be the 2 ith voter name in the lexicographic order. It follows that the chair's goal can be reached by at most $k$ deletions of voters if and only if $\left(\exists b_{1}\right)\left(\forall b_{2}\right) \cdots\left(\exists b_{2 \ell-1}\right)\left(\forall b_{2 \ell}\right)\left[F\left(x_{1}:=b_{1}, x_{2}:=b_{2}, \ldots, x_{2 \ell}:=\right.\right.$ $b_{2 \ell}$ ) evaluates to true], which is true if and only if $F \in \mathrm{QBF}^{\prime}$.

PSPACE-hardness of online- $\mathscr{E}$-CCAV for the election system $\mathscr{E}$ defined above can be shown via essentially the same $\leq_{m}^{p}$-reduction from $\mathrm{QBF}^{\prime}$. The only difference is that we now map the given $\mathrm{QBF}^{\prime}$ instance $F$ to an instance of online- $\mathscr{E}-\mathrm{CCAV}$, which is defined exactly as the online- $\mathscr{E}$-CCDV instance constructed above, except that all voters $v_{i}$ with $i \equiv 0 \bmod 3$ are specified as registered voters, and all other voters are unregistered. The correctness argument is analogous.

The destructive cases can be shown analogously, by modifying the election system $\mathscr{E}$ defined above as follows, yielding our modified system $\mathscr{E}^{\prime}$ : Whenever everyone loses (wins) in $\mathscr{E}$, everyone wins (loses) in $\mathscr{E}^{\prime}$. It follows from Theorem 4.1 and the above $\leq_{m}^{p}$-reduction from $\mathrm{QBF}^{\prime}$ that online- $\mathscr{E}^{\prime}-$ DCDV and online- $\mathscr{E}^{\prime}-\mathrm{DCAV}$ are both PSPACE-complete.

For control by deleting or adding voters, the deletion or addition limit $k$ is-both in the nononline case and in our online definition (which is what is used in Theorem 4.2) - part of the problem instance. To better understand the source of the tremendous level of computational hardness Theorem4.2]showed that these problems can have, let us now consider restrictions of these problems in which the deletion or addition limit is bounded by a constant. For a given election system $\mathscr{E}$ and a fixed $k$, let online- $\mathscr{E}-\mathrm{CCDV}[k]$ be the restriction of online- $\mathscr{E}-\mathrm{CCDV}$ to those inputs whose deletion limit is at most $k$, and define the problem variant online- $\mathscr{E}-\operatorname{CCAV}[k]$ analogously. We will show in

Theorem 4.4 that this change in the definition-bounding the deletion/addition bound-brings the complexity of these problems from PSPACE down to coNP. (In contrast, limiting the number of candidates to two was shown by Theorem 4.2 to leave these two problems PSPACE-complete.)

The coNP upper bound follows immediately from the following theorem about restricted polynomial-time alternating Turing machines, which is of interest in its own right. If we define the weight of a path of an alternating Turing machine to be the number of 1 's in the existential guesses along the path, what Theorem 4.3 says is that the class of languages accepted by polynomial-time alternating Turing machines whose accepting paths are weight-bounded is precisely coNP.

Theorem 4.3 Let $k \geq 0$. The class of languages accepted by polynomial-time alternating Turing machines that satisfy the property that on each accepting computation path the number of existential guesses on which the bit is guessed as 1 is at most $k$ is precisely coNP.

Proof. We will show this by induction on $k$. It is immediate that the $k=0$ case is precisely coNP. To prove the inductive step, let $k>0$ and let $A$ be a language accepted by a polynomialtime alternating Turing machine that satisfies the property that on each accepting computation path the number of existential guesses on which the bit is guessed as 1 is at most $k$. (That is, any path that contains at least $k+1$ guessed 1's in its existential guesses must have as its (leaf) value Reject rather than Accept. Recall that each path of a polynomial-time alternating Turing machine has as its individual (leaf) value either Accept or Reject, and the overall action of the Turing machine is determined by the thought-experiment of applying the existential and universal node actions of the machine to those leaf values, resulting in an Accept or Reject at the root that determines the machine's acceptance or rejection on the given input.) We will show that $A$ is in coNP.

Throughout this proof, all $x_{i}$ 's and $y_{i}$ 's are over $\{0,1\}$, i.e., are bits.
Let $B$ be a polynomial-time computable ternary predicate and let $\ell(n)$ be a polynomial such that for all $x, x \in A$ if and only if

$$
\forall x_{1} \exists y_{1} \forall x_{2} \exists y_{2} \ldots \forall x_{\ell(|x|)} \exists y_{\ell(|x|)}\left(B\left(x, x_{1} \ldots x_{\ell(|x|)}, y_{1} \ldots y_{\ell(|x|)}\right) \wedge \sum_{i=1}^{\ell(|x|)} y_{i} \leq k\right)
$$

Such a polynomial and predicate exist, since we can add extra quantifiers with dummy variables to make the quantifiers alternating and we can always guess an existentially-quantified dummy variable as 0 .

We can rewrite the above as follows. For all $x, x \in A$ if and only if

$$
\begin{aligned}
& \forall x_{1} \quad\left(\forall x_{2} \exists y_{2} \quad \forall x_{3} \exists y_{3} \quad \ldots \quad \forall x_{\ell(|x|)} \exists y_{\ell(|x|)} \quad\left(B\left(x, x_{1} \ldots x_{\ell(|x|)}, 1 y_{2} \ldots y_{\ell(|x|)}\right) \wedge \sum_{i=2}^{\ell(|x|)} y_{i} \leq k-1\right) \vee\right. \\
& \forall x_{2} \quad\left(\forall x_{3} \exists y_{3} \quad \ldots \quad \forall x_{\ell(|x|)} \exists y_{\ell(|x|)} \quad\left(B\left(x, x_{1} \ldots x_{\ell(|x|)}, 01 y_{3} \ldots y_{\ell(|x|)}\right) \wedge \sum_{i=3}^{\ell(|x|)} y_{i} \leq k-1\right) \vee\right. \\
& \forall x_{3} \quad\left(\ldots \quad \forall x_{\ell(|x|)} \exists y_{\ell(|x|)} \quad\left(B\left(x, x_{1} \ldots x_{\ell(|x|)}, 001 y_{4} \ldots y_{\ell(|x|)}\right) \wedge \sum_{i=4}^{\ell(|x|)} y_{i} \leq k-1\right) \vee\right. \\
& \begin{aligned}
\forall x_{\ell(|x|)} \quad & \left(B\left(x, x_{1} \ldots x_{\ell(|x|)}, 0^{\ell(|x|)-1} 1\right) \wedge \sum_{i=\ell(|x|)+1}^{\ell(|x|)} y_{i} \leq k-1\right) \vee \\
& \left.\left.\left.B\left(x, x_{1} \ldots x_{\ell(|x|)}, 0^{\ell(|x|)}\right) \ldots\right)\right)\right) .
\end{aligned}
\end{aligned}
$$

(Of course, $\sum_{i=\ell(|x|)+1}^{\ell(|x|)} y_{i} \leq k-1$ is true, since $k>0$ in the present case.) The long expression above is not quite in the right form to apply the inductive hypothesis. In order to be able to do so, define language $C$ such that $\left\langle x, x_{1} \ldots x_{r}\right\rangle \in C$ if and only if $r \leq \ell(|x|)$ and

$$
\forall x_{r+1} \exists y_{r+1} \ldots \forall x_{\ell(|x|)} \exists y_{\ell(|x|)}\left(B\left(x, x_{1} \ldots x_{\ell(|x|)}, 0^{r-1} 1 y_{r+1} \ldots y_{\ell(|x|)}\right) \wedge \sum_{i=r+1}^{\ell(|x|)} y_{i} \leq k-1\right) .
$$

Clearly $C$ can be accepted by a polynomial-time alternating Turing machine that satisfies the property that on each accepting computation path the number of existential guesses on which the bit is guessed as 1 is at most $k-1$. By the inductive hypothesis, $C$ is in coNP. Since $x \in A$ if and only if

$$
\begin{aligned}
& \forall x_{1}\left(\langle x , x _ { 1 } \rangle \in C \vee \forall x _ { 2 } \left(\langle x , x _ { 1 } x _ { 2 } \rangle \in C \vee \forall x _ { 3 } \left(\left\langle x, x_{1} x_{2} x_{3}\right\rangle \in C \vee\right.\right.\right. \\
& \left.\left.\quad \ldots \forall x_{\ell(|x|)}\left(\left\langle x, x_{1} x_{2} x_{3} \ldots x_{\ell(|x|)}\right\rangle \in C\right) \vee B\left(x, x_{1} \ldots x_{\ell(|x| \mid}, 0^{\ell(|x|)}\right) \ldots\right)\right),
\end{aligned}
$$

it follows that $A$ is in coNP. (Why is it in coNP? Note that its complement is in NP due to having a polynomial-length witnesses. Let $N$ be a fixed NP Turing machine accepting $\bar{C}$. Our witness scheme for membership in $\bar{A}$ is: Guess an $x_{1}, \ldots, x_{\ell(|x|)}$ such that $B\left(x, x_{1} \ldots x_{\ell(|x|)}, 0^{\ell(|x|)}\right)$ holds and also guess for each of $\left\langle x, x_{1}\right\rangle,\left\langle x, x_{1} x_{2}\right\rangle, \ldots,\left\langle x, x_{1} x_{2} \ldots x_{\ell(|x|)}\right\rangle$ an accepting path of $N$ on that input.)

Theorem 4.4 For each $k \geq 0$, the following hold:

1. (a) For each election system $\mathscr{E}$ with a polynomial-time winner problem, online- $\mathscr{E}-\mathrm{CCDV}[k]$ is in coNP. (b) There exists an election system $\mathscr{E}$ with a polynomial-time winner problem such that online- $\mathscr{E}-\mathrm{CCDV}[k]$ is coNP-complete, even when limited to two candidates.
2. (a) For each election system $\mathscr{E}$ with a polynomial-time winner problem, online- $\mathscr{E}-\mathrm{CCAV}[k]$ is in coNP. (b) There exists an election system $\mathscr{E}$ with a polynomial-time winner problem such that online- $\mathscr{E}-\mathrm{CCAV}[k]$ is coNP-complete, even when limited to two candidates.

Proof Sketch. Parts 1(a) and 2(a) follow immediately from Theorem 4.3.
Now consider part 1(b). Even for $k=0$ (and in effect so for all $k$, as those have within them $k=0$ as subcases we can map to) we claim that there is an election system $\mathscr{E}$ with a polynomial-time winner problem such that online- $\mathscr{E}-\mathrm{CCDV}[k]$ is easily shown to be coNP-hard, namely by a $\leq_{m^{-}}^{p}$ reduction from the coNP-complete tautology problem. The mapping and $\mathscr{E}$ are inspired by the proof of Theorem 4.2. We use the lexicographically least candidate name to be a proposed tautology and we use the voters as tests of various assignments to it (if the assignment satisfies, everyone wins). So the problem can force the chair's top choice (candidate $a$, see the proof of Theorem 4.2) to win exactly if the formula is a tautology. As in the statement and proof of Theorem 4.2, this reduction maps to outputs having only two candidates.

The proof sketch for part 2(b) (online- $\mathscr{E}-\mathrm{CCAV}[k]$ ) is similar to that of part $1(\mathrm{~b})$. The first (and current) voter in our reduction is unregistered (but with $k=0$ she obviously cannot be added), and the remaining voters are testing assignments to a proposed tautology and we have only two candidates, just as in the above proof sketch for online- $\mathscr{E}$-CCDV $[k]$.

### 4.2 Control by Partition of Voters

Theorem 4.5 There exist election systems $\mathscr{E}$ and $\mathscr{E}^{\prime}$, whose winner problems can be solved in polynomial time, such that online- $\mathscr{E}-\mathrm{CCPV}$ and online- $\mathscr{E}^{\prime}$-DCPV are PSPACE-complete, even when limited to two candidates.

Proof. This proof is similar in flavor to the proof of Theorem4.2, but since we now handle control by partition of voters, there are some decisive differences.

The election system $\mathscr{E}$ is now defined as follows.
Case 1: There is a candidate named RoundOne, and no voter is named Marker. In this case, everyone loses.

Case 2: There is a candidate named RoundOne and a voter named Marker. In this case, interpretin our fixed, natural encoding-the lexicographically least candidate not named RoundOne as a boolean formula, $\Phi$, whose variable names must be the strings $x_{1}, x_{2}, \ldots, x_{2 \ell}$ for some $\ell$, and $x_{2 \ell}$ must actually appear in $\Phi$ (the others do not have to, but no variable other than $x_{1}, x_{2}, \ldots, x_{2 \ell}$ can appear in $\left.\Phi\right)$. If this candidate is not of the required syntactic form, exactly RoundOne wins. If the candidate set does not consist of exactly RoundOne and the above candidate, then exactly RoundOne wins. If the voter list consists of exactly $2 \ell+1$ voters such that one voter is named Marker, one voter is named $v_{1}^{\text {yes }}$ or $v_{1}^{\text {no }}$, one voter is named $v_{2}$, one voter is named $v_{3}^{\text {yes }}$ or $v_{3}^{\text {no }}, \ldots$, one voter is named $v_{2 \ell-1}^{\text {yes }}$ or $v_{2 \ell-1}^{\text {no }}$, and one voter is named $v_{2 \ell}$, where all subscripts are given in binary, then assign the $2 \ell$ variables of $\Phi$ as follows. (If the voter list is not exactly that then exactly RoundOne wins.) For each odd $i, 1 \leq i \leq 2 \ell-1$, set $x_{i}$ to true if there is a voter named $v_{i}^{\text {yes }}$ and to false if there is a voter named $v_{i}^{\text {no }}$. For each even $i$, $2 \leq i \leq 2 \ell$, set $x_{i}$ to true if the voter named $v_{i}$ has the property that in her preference order RoundOne is the top choice, and otherwise set $x_{i}$ to false. If this assignment makes $\Phi$ true, then the candidate not named RoundOne is the only winner, otherwise (exactly) RoundOne wins.

Case 3: There is no candidate named RoundOne. In this case, everyone wins.
This ends the specification of $\mathscr{E}$. Clearly, $\mathscr{E}$ has a polynomial-time winner problem, since it is just evaluating a fully specified and assigned boolean formula, and doing various syntactic checks.

Our online control by partition of voters problems are all in PSPACE by Theorem 4.1 To prove PSPACE-hardness, we again $\leq_{m}^{p}$-reduce from the PSPACE-complete problem $\mathrm{QBF}^{\prime}$ defined in the proof of Theorem 4.2 Let $F\left(x_{1}, \ldots, x_{2 \ell}\right)$ be a given $\mathrm{QBF}^{\prime}$ instance, where $x_{2 \ell}$ actually occurs in $F$. (If our input is syntactically incorrect, then map it to a fixed nonmember of our target problem.) Our candidate set will be $C=\{$ RoundOne, $a\}$, where $a$ will in her name encode $F$ (without loss of generality, that will not form the string "RoundOne"), $a$ will be our distinguished candidate, our current voter will be $u=\tilde{v}_{0}$, the chair's preference order will be $a>_{\sigma}$ RoundOne, and there will be $3 \ell+1$ voters who vote in order $\tilde{v}_{0}, \tilde{v}_{1}, \ldots, \tilde{v}_{3 \ell}$, where $\tilde{v}_{0}$ is named Marker, and the remaining voters are named as follows:

| voter | $\tilde{v}_{1}$ | $\tilde{v}_{2}$ | $\tilde{v}_{3}$ | $\tilde{v}_{4}$ | $\tilde{v}_{5}$ | $\tilde{v}_{6}$ | $\cdots$ | $\tilde{v}_{3 \ell-2}$ | $\tilde{v}_{3 \ell-1}$ | $\tilde{v}_{3 \ell}$ |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: |
| name | $v_{1}^{\text {yes }}$ | $v_{1}^{\text {no }}$ | $v_{2}$ | $v_{3}^{\text {yes }}$ | $v_{3}^{\text {no }}$ | $v_{4}$ | $\cdots$ | $v_{2 \ell-1}^{\text {yes }}$ | $v_{2 \ell-1}^{\text {no }}$ | $v_{2 \ell}$ |

This ends our statement of the reduction. Why does it work?
If $F \in \mathrm{QBF}^{\prime}$, then

$$
\begin{align*}
& \left(\exists b_{1}\right)\left(\forall b_{2}\right) \cdots\left(\exists b_{2 \ell-1}\right)\left(\forall b_{2 \ell}\right)  \tag{1}\\
& {\left[F\left(x_{1}:=b_{1}, x_{2}:=b_{2}, \ldots, x_{2 \ell}:=b_{2 \ell}\right) \text { evaluates to true }\right],}
\end{align*}
$$

where the $b_{i} \in\{0,1\}$ are truth assignments. So the partition that puts Marker and all voters $v_{i}, i$ even, on one side, say into $V_{\text {left }}$, and for each $v_{i}^{\text {yes }} / v_{i}^{\text {no }}$ pair, $i$ odd, follows (1) by putting $v_{i}^{\text {yes }}$ into $V_{\text {left }}$ and $v_{i}^{\text {no }}$ into $V_{\text {right }}$ if $b_{i}=1$, and $v_{i}^{\text {no }}$ into $V_{\text {left }}$ and $v_{i}^{\text {yes }}$ into $V_{\text {right }}$ if $b_{i}=0$ (and crucially note that the preference orders of the $v_{i}, i$ even, we will have seen in the future can (in the future) effect the future partition choices), will by Case 2 have one first-round election (namely, $\left(C, V_{\text {left }}\right)$ ) in which $a$ is the only winner. And in the other first-round election, $\left(C, V_{\text {right }}\right)$, by Case 1 everyone, including RoundOne, loses. Thus, only $a$ proceeds to the second-round runoff election, where by Case 3 everyone wins, i.e., our distinguished candidate $a$ wins.

In the other direction, suppose $F$ is syntactically correct, and it is possible by some partition of voters to force " $a$ or better" (so $a$ ) to be a winner. Since RoundOne is in both first-round elections (so Case 3 cannot occur), the only way candidate $a$ can be guaranteed to even survive at least one first-round election is if we can guarantee that Case 2 is satisfied. But that means that $F \in \mathrm{QBF}^{\prime}$.

Since our reduction can be computed in polynomial time, this shows that online- $\mathscr{E}$-CCPV is PSPACE-hard.

To show that online- $\mathscr{E}^{\prime}$-DCPV is PSPACE-hard, we modify the election system $\mathscr{E}$ defined above as follows, yielding our modified system $\mathscr{E}^{\circ}$ : Most crucially, Case 2 of the election system description changes to now making everyone lose if $\Phi$ evaluates to true under the specified assignment, and if $\Phi$ evaluates to false (or there is any syntactic problem regarding who is in the voter list) then everyone wins. Case 3 changes to now having everyone lose, and Case 1 stays the same. The $\leq_{m}^{p}$-reduction from $\mathrm{QBF}^{\prime}$ remains the same, except that the chair's preference order will now be reversed to RoundOne $>_{\sigma} a$, and with these changes the reduction can be shown to work correctly by arguments analogous to those in the constructive case.

The above proof establishes that there are election systems, with polynomial-time winner problems, for which constructive and destructive online control by partition of voters are PSPACEcomplete even when limited to two candidates. Can we make do with one candidate and still have PSPACE-hardness? The following result shows that if we could, then PSPACE would equal $\mathrm{NP} \cap \mathrm{coNP}{ }^{6}$

Theorem 4.6 1. For each election system $\mathscr{E}$ with a polynomial-time winner problem, the problems online- $\mathscr{E}-\mathrm{CCPV}$ and online- $\mathscr{E}-\mathrm{DCPV}$ when limited to one candidate are in NP .
2. There exist election systems $\mathscr{E}$ and $\mathscr{E}^{\prime \prime}$ with polynomial-time winner problems such that the problems online- $\mathscr{E}-\mathrm{CCPV}$ and online- $\mathscr{E}^{\prime}$-DCPV, even when restricted to one candidate, are NP-complete.

[^5]Proof. We give the proof for the destructive case. For the first part, with one candidate, $c$, every voter has the same preference as her full vote: $c$. So there is no sequentially revealed information, as in our model we know the voter names (and their order but here that does not matter) as part of our input. So we just in NP can guess every partition of the voters from $u$, the current voter, onward, and see if one of those meets the chair's destructive goal, " $c$ does not win."

For the second part, membership in NP follows from the first part. As to NP-hardness, let us $\leq_{m}^{p}$-reduce from SAT. The election system, $\mathscr{E}^{\prime}$, is defined as follows:

Case 1: If there are two or more candidates, everyone wins.
Case 2: If there is one candidate and that candidate's name gives a syntactically correct boolean formula $\varphi$ that has, say, $k$ variables, and there are exactly $k$ voters, and if we set the $i$ th variable of $\varphi$ to true exactly if 1 is the lowest order bit of the voter whose name ranks ith in lexicographic order among the voters' names, then $\varphi$ is satisfied either by that assignment or by the bitwise complemented twin of that assignment, then everyone loses.

Case 3: In all other cases (including syntactical problems), everyone wins.
The reduction SAT $\leq_{m}^{p}$ online- $\mathscr{E}^{\prime}$-DCPV is defined as follows. Given a boolean formula $F\left(x_{1}, \ldots, x_{k}\right)$, where without loss of generality all variables actually appear in $F$, we construct an online- $\mathscr{E}^{\prime}$-DCPV instance with candidate set $C=\{c\}$, where $c$ encodes $F$, the voters are named (in binary) $1,2, \ldots, 2 k$ and they vote in this order, $u=1$ is the current voter, the distinguished candidate is $c$, and the chair's preference order $\sigma$ is $c$. Clearly, $c$ can be made not a winner if and only if $F$ is satisfiable. Why?

First, if $F$ is satisfiable then we can determine a satisfying assignment by the partition choices we make among each voter pair $(2 i-1,2 i), 1 \leq i \leq k$, by choosing exactly one per pair for the righthand side of the partition, such that the left-hand side of the partition has the bit-wise complement of that same satisfying assignment. So, by the definition of $\mathscr{E}^{\prime}, c$ will not be a winner in either first-round subelection, and so will not even be in the final runoff election, which will have zero candidates, and so $c$ will not be a winner.

Second, if $c$ loses, by the election rule that proves that (Case 2 in the definition of $\mathscr{E}^{\prime}$ ), $F$ is satisfiable.

The constructive case can be shown analogously.

## Corollary 4.7 The following three statements are equivalent:

## 1. $\mathrm{PSPACE}=\mathrm{NP} \cap \mathrm{coNP}$.

2. There exists an election system $\mathscr{E}$ with a polynomial-time winner problem such that online- $\mathscr{E}$-DCPV is PSPACE-hard when restricted to one candidate.
3. There exists an election system $\mathscr{E}$ with a polynomial-time winner problem such that online- $\mathscr{E}$-CCPV is PSPACE-hard when restricted to one candidate.

Proof. To show equivalence of the first two statements, suppose PSPACE $=\mathrm{NP} \cap$ coNP. So PSPACE $=$ NP. The second statement now follows from the second part of Theorem 4.6, Conversely, by the second part's hypothesis and the first part of Theorem4.6 we have PSPACE $\subseteq$ NP, which (since PSPACE $=$ coPSPACE) is equivalent to PSPACE $=\mathrm{NP} \cap$ coNP. The equivalence of the first and the third statements is proven analogously.

The analogues of the destructive cases of both parts of Theorem 4.6 also hold when "online" is removed, i.e., for the problem $\mathscr{E}$-DCPV. In contrast, the constructive non-online analogue of Theorem 4.6s first part can be strengthened to a P upper bound. (Why can we get a P result here but not in Theorem 4.6? The proof of the following result does not apply if some voters are already committed to sides of the partition-it is assuming (and truly using the fact) that we have full control of where all voters go. But in the online setting, the current voter $u$ can be a voter who does not come first and so some voters may already be assigned to sides of the partition. And why do we get P for constructive but not destructive? The effect the following proof uses is specific to the constructive case.)

Theorem 4.8 For each election system $\mathscr{E}$ with a polynomial-time winner problem, $\mathscr{E}-\mathrm{CCPV}$, when restricted to one candidate, is in P .

Proof. For the one candidate to win, she certainly must win the runoff, in which all voters vote. Also, if she does win when all voters vote, then she can easily be made to survive the first round, using the partition structure $(V, \emptyset)$. It follows from these two observations that constructive (nononline) control by partition of voters is possible if and only if the one candidate wins in the election with voter list $V$.

## 5 Online Control for Plurality

We have seen in the previous section that online control can be very hard, namely PSPACEcomplete, even for voting systems whose winners can be determined in polynomial time. In this section, we study online control for plurality voting. In this very simple yet popular voting system, every voter gives one point to her most preferred candidate, and all candidates with the most points win. It is known that non-online control by adding and by deleting voters can be done in polynomial time, both in the constructive case (since the two relevant unique-winner-model results of [BTT92] as noted in [FHH14] also hold in the nonunique-winner model) and in the destructive case (since we have checked and here state as true that those unique-winner-model results of [HHR07] are easily seen to also hold in the nonunique-winner model). We now show that the corresponding types of online control are also easy.

Theorem 5.1 The problems online-plurality-CCDV, online-plurality-CCAV, online-plurality-DCDV, and online-plurality-DCAV are in P .

Proof. For online-plurality-CCDV, let $(C, u, V, \sigma, d)$ be a given basic OVCS, augmented by the additional information of online control by deleting voters: a deletion upper bound $k$, for each voter $v$ before $u$ a flag saying if $v$ was deleted and the vote cast by $v$ (if not deleted), where at most $k$
voters can be marked as deleted, and a vote to cast for $u$ (if $u$ is not to be deleted). If $d$ is the chair's bottom choice in $\sigma$, we are done, since the input then is trivially in online-plurality-CCDV (unless it is syntactically illegal). If exactly $k$ voters have been marked as already deleted, we can do no more deletions, so $u$ and all later voters go in, and we assume (as this is the most challenging case) that all later voters vote for one particular candidate in $\Lambda_{d}=\left\{c \in C \mid c{ }_{\sigma} d\right\}$ that among the candidates in $\Lambda_{d}$ has the most first place votes after $u$ is put in, and so we can easily answer the online control question. If less than $k$ voters have been selected already for deletion, then delete $u$ if and only if $u$ 's top choice is a highest scoring (with respect to the voters before $u$ ) candidate in $\left\{c \in C \mid c<_{\sigma} d\right\}$. Then assume that all later voters vote for one particular candidate in $\Lambda_{d}=\left\{c \in C \mid c<_{\sigma} d\right\}$ that among the candidates in $\Lambda_{d}$ has the most first place votes after $u$ is put in. And assume we delete as many of those as the deletion amount left (after $u$ ) allows. It is easy to see whether this results in " $d$ or better" being a winner (in which case our algorithm answers "yes") or not (in which case our algorithm answers "no"). (One might comment that it would suffice, especially to just handle the decision version, to follow the very simple "operational" approach mentioned on page 4 of Section 2 However, we have given a more dynamic description of the process both as we want to make clear how the chair can decide what action to take at each point and as the description above is also helping establish the correctness of the actions taken.)

For online-plurality-CCAV, let $(C, u, V, \sigma, d)$ be a given basic OVCS, augmented by the additional information of online control by adding voters: an addition upper bound $k$, for each voter the information of whether she is registered or not, and for each unregistered voter before $u$ the information of whether she has been added or not, the vote of each registered or added voter before $u$, and $u$ 's potential vote. Again, the question is trivial if $d$ is the chair's bottom choice in $\sigma$. Otherwise, we can see what $u$ 's vote is and if $k$ has yet been reached. If $k$ has not been reached yet, we add $u$ if and only if $u$ 's top choice belongs to $\left\{c \in C \mid c \geq_{\sigma} d\right\}$. ${ }^{7}$ And in the worst case all future voters vote for the same member of $\left\{c \in C \mid c<_{\sigma} d\right\}$, which will be one that after $u$ votes has the most first-place votes among those.

The two destructive cases can be handled analogously. The main differences are, in both cases, that the question now is trivial to decide if $d$ is the chair's top choice in $\sigma$; in the deleting-voters case, that $u$ is to be deleted (provided the deletion limit $k$ has not been reached yet) if and only if $u$ 's top choice is a highest scoring (with respect to the voters before $u$ ) candidate in $\left\{c \in C \mid c \leq{ }_{\sigma} d\right\}$; and in the adding-voters case, that $u$ is to be added (provided the addition limit $k$ has not been reached yet) if and only if $u$ 's top choice belongs to $\left\{c \in C \mid c>_{\sigma} d\right\}$. And, in both cases, we again assume that all future votes will belong to some particular member of $\left\{c \in C \mid c \leq_{\sigma} d\right\}$ that after $u$ votes has the most first-place votes among those candidates.

Non-online control by partition of voters, in the model we feel is most natural and have adopted in this paper (called "ties promote"), is NP-complete in both the constructive and destructive cases (HHR07] showed this in the unique-winner model, and we have checked and here state that NPcompleteness also holds for the nonunique-winner model analogues). In contrast, the corresponding types of online control are both coNP-hard. This implies that these problems cannot be in NP, unless

[^6]$\mathrm{NP}=\mathrm{coNP}$, which is considered to be highly unlikely. It remains open whether or not they are in coNP; we conjecture that they are not.

Theorem 5.2 online-plurality-CCPV and online-plurality-DCPV are coNP-hard.
Proof. We prove this by a reduction from the complement of the following NP-complete problem, Hitting Set: Given a set $B=\left\{b_{1}, \ldots, b_{m}\right\}$, a nonempty collection $\mathscr{S}=\left\{S_{1}, \ldots, S_{n}\right\}$ of subsets of $B$, and a positive integer $k \leq m$, does $\mathscr{S}$ have a hitting set of size at most $k$, i.e., does there exist a set $B^{\prime} \subseteq B$ such that $\left\|B^{\prime}\right\| \leq k$ and for all $S_{i} \in \mathscr{S}, S_{i} \cap B^{\prime} \neq \emptyset$.

We turn an instance ( $B, \mathscr{S}, k$ ) of Hitting Set into the following instance of online partition of voters. The set of candidates is $\left\{c, w, b_{1}, \ldots, b_{m}\right\} \cup A$, where $A=\left\{a_{i} \mid 1 \leq i \leq 4 m n k+1\right\}$. The current voter is $u$. The votes before $u$ that are on the left side of the partition are exactly the same as the votes before $u$ that are on the right side of the partition. Both sides of the partition consists of the following votes.

- $4 n k$ votes $c>w>\cdots$, where $\cdots$ denotes that the remaining candidates follow in some arbitrary order.
- $4 n k$ votes $w>c>\cdots$.
- For every $i, 1 \leq i \leq n, 2 k$ votes $S_{i}>c>\cdots$, where $S_{i}$ denotes the candidates in $S_{i}$ in some arbitrary order.
- For every $j, 1 \leq j \leq m$, as many votes $b_{j}>B-\left\{b_{j}\right\}>c>w>\cdots$ as needed to make the score of $b_{j}$ equal to $4 n k-1$ in this subelection.
- For every $i, 1 \leq i \leq 4 m n k$, one vote $a_{i}>c>\cdots$ and one vote $a_{i}>w>\cdots$.

Voter $u$ votes $a_{4 m n k+1}>w>\cdots$. And there are $k$ voters after $u$. The chair's top choice is $c$ and the chair's bottom choice is $w$, and the distinguished candidate is $c$ in the constructive case (i.e., for online-plurality-CCPV) and $w$ in the destructive case (i.e., for online-plurality-DCPV).

A simple but crucial observation is that no candidate $a \in A$ will ever make it to the final round, since her score in the first round in either subelection will be at most $2+k$, which is less than $c$ 's score in that subelection. If both $c$ and $w$ participate in the final round, $c$ gains $8 m n k$ points, $w$ gains $8 m n k+1$ points, and no other candidate gains points from the voters specified above whose top choice was in $A$.

We will show that $\mathscr{S}$ does not have a hitting set of size at most $k$ if and only if $c$ can always be made a winner in the constructed election, and we will show that $\mathscr{S}$ does not have a hitting set of size $k$ if and only if $w$ can always be made to not be a winner in the constructed election. This proves the theorem.

First suppose that $\mathscr{S}$ has a hitting set of size at most $k$. Let $B^{\prime}$ be a hitting set of size $k . B^{\prime}$ exists, since $k \leq m$. Let the $k$ voters after $u$ vote such that the top choice of the $i$ th voter is the $i$ th candidate in $B^{\prime}$. Then, no matter how we partition the voters, the set of candidates that participate in the final round is $\{c, w\} \cup B^{\prime}$. The scores in the final round are as follows: (a) $\operatorname{score}(c)=8 n k+8 m n k$,
(b) $\operatorname{score}(w)=8 n k+8 m n k+1$, and (c) $\sum_{b \in B^{\prime}} \operatorname{score}(b)=8 m n k-2 m+k$. It follows that $c$ is not a winner and that $w$ is a winner.

For the converse, suppose that $\mathscr{S}$ does not have a hitting set of size at most $k$. Partition by putting $u$ and all voters after $u$ in the same first-round election. Then the set of candidates in the final round is $\{c, w\} \cup B^{\prime}$, where $B^{\prime} \subseteq B$ and $\left\|B^{\prime}\right\| \leq k$. Since $B^{\prime}$ is not a hitting set, in the final round $c$ gains at least $4 k$ points from voters voting $S_{i}>c>\cdots$ such that $S_{i} \cap B^{\prime}=\emptyset$. Thus in the final election the following hold: (a) $\operatorname{score}(c) \geq 8 n k+8 m n k+4 k$, (b) $\operatorname{score}(w) \leq 8 n k+8 m n k+1+k$, and (c) $\sum_{b \in B^{\prime}} \operatorname{Score}(b) \leq 8 m n k-2 m+k$. It follows that $c$ is the unique winner of this election.

## 6 Conclusions and Open Questions

Inspired by the maxi-min approach of online algorithms, we studied online voter control in sequential voting. We showed that for suitably constructed election systems with polynomial-time winner problems, the resulting voter-control problems can be extremely hard, namely PSPACE-complete, even for just two candidates. We additionally obtain coNP-completeness for the deleting/addingvoter cases, even for just two candidates, when there is a bounded deletion/addition limit. For plurality, things are easier still: Online control by deleting or adding voters is in polynomial time for plurality, just as in the non-online case.

Attractive future directions include the study of additional natural election systems. Can one obtain PSPACE-completeness results for highly natural, existing systems, for example? Another interesting direction would be to investigate online control through a typical-case analysis of heuristic approaches (such as, for example, [MPS08, HH09] do rigorously in a winner-problem setting, see also [RS13]).

[^1]:    ${ }^{1}$ An exception is a paper by Fitzsimmons, Hemaspaandra, and Hemaspaandra [FHH13] that is, regarding their earliest appearing versions, more recent than the present paper, and studies a mixed model involving both a chair and manipulators, in which the manipulative voters set their votes after actions by the chair.

[^2]:    ${ }^{2}$ Actually, as our previous example suggested, our model is a bit more flexible and allows one to ask such questions starting at an intermediate point at which some actions have already been taken, potentially by a different admissions staff member.

[^3]:    ${ }^{3}$ Note that this maxi-min-inspired (but with more quantifiers) approach is really about alternating quantifiers. We are asking if there exists a current action of the chair, such that for all potential revealed vote values that come between now and the next time the chair has to decide on an action, there exists a next action by the chair, such that for all ...... the chair reaches her goal.
    ${ }^{4}$ Why do we provide an ordering $\sigma$ rather than just providing as a list the set of candidates who are good enough to count as reaching our goal? For the decision-problem version of online voter control, which is our formulation here, providing such a set would be just as good. But by making $\sigma$ a part of the input, we make the model compatible, for the future, with the interesting optimization problem of trying to find the most preferred candidate within $\sigma$ for which the chair can ensure that there is among the winner set one of the candidates in the segment from that candidate to the top candidate in $\sigma$.

    Also, to avoid any confusion, we note that in our " $d$ chooses an upper (constructive case) or lower (destructive case) segment of the candidates" approach, the non-online version's situation that the destructive goal "opposing" a constructive goal is specified in the same way not longer holds (although we could have defined things in a less natural way so that that would hold). That is, in the non-online setting, the distinguished candidate $d$ in the constructive case is saying who the chair wants to win, and in the destructive case is saying who the chair wants to not win; $d$ in one case is defined in the problem definition to denote the beloved candidate and in the other case is defined to denote the despised candidate. However, in our case, we are giving an order $\sigma$, and it would be perverse and confusing to have $>$ mean one thing for constructive and another for destructive. And so, as we have defined things, if the chair's stated ordering $\sigma$ is $v_{1}>v_{2}>v_{3}>v_{4}>v_{5}$ and $d=v_{2}$, in the constructive case that means that the chair wants at least one of $v_{1}$ or $v_{2}$ to win. To state the destructive-case goal-which in some sense is the "flip" of that constructive-case goal-of having neither $v_{1}$ nor $v_{2}$ be a winner, one would give as the chair's ordering $v_{5}>v_{4}>v_{3}>v_{2}>v_{1}$ and $d=v_{2}$, since this specifies that $v_{2}$ and $v_{1}$ are the chair's two most despised candidates and are the ones the chair wants to prevent from being winners.

    These comments simply refer to the way various "opposite" goals happen to be expressed. None of the above is saying that the constructive problem (viewed as a set) and the destructive problem (viewed as a set) are each other's complements. Due to the quantification involved regarding the actions being taken such as by the chair, that is not true.

[^4]:    ${ }^{5}$ The statement of Theorem4.1 holds even for election systems whose winner problems are in PSPACE.

[^5]:    ${ }^{6}$ Are elections with just one candidate even ever interesting in the real world? We feel they sometimes are. For example, a popular referendum-or for that matter a vote in a legislature on a bill-is essentially an up-or-down vote on one "candidate." So is a vote on whether to recall an elected official, or to impeach a judge, or to ratify a person who has been nominated for a sports hall of fame.

[^6]:    ${ }^{7}$ Sure enough, $u$ 's top choice could be one of those candidates that end up having only few votes, so adding $u$ could be a wasted addition that will block some future good addition in some vote sequences, but in the worst case all future voters put first a candidate disliked by the chair; so our action is fine within the quantifier structure of the problem.
