Abstract Consider a dynamic programming scheme for a decision problem in which all subproblems involved are also decision problems. An implementation of such a scheme is *positive-instance driven* (PID), if it generates positive subproblem instances, but not negative ones, building each on smaller positive instances.

We take the dynamic programming scheme due to Bouchitté and Todinca for treewidth computation, which is based on minimal separators and potential maximal cliques, and design a variant (for the decision version of the problem) with a natural PID implementation. The resulting algorithm performs extremely well: it solves a number of standard benchmark instances for which the optimal solutions have not previously been known. Incorporating a new heuristic algorithm for detecting safe separators, it also solves all of the 100 public instances posed by the exact treewidth track in PACE 2017, a competition on algorithm implementation.

We describe the algorithm, prove its correctness, and give a running time bound in terms of the number of positive subproblem instances. We perform an experimental analysis which supports the practical importance of such a bound.

Keywords treewidth \cdot tree decomposition \cdot dynamic programming \cdot positive-instance driven

1 Introduction

Suppose we design a dynamic programming algorithm for some decision problem, formulating subproblems, which are decision problems as well, and recurrences among those subproblems. A standard approach is to list all subproblem instances and scan the list from "small" ones to "large", deciding the answer, positive or negative, to each instance by means of these recurrences. When the number of positive subproblem instances are expected to be

 $^{^{\}star}\,$ A preliminary and an abridged version of this paper was presented at the 25th European Sysmposium on Algorithms

much smaller than the total number of subproblem instances, a natural alternative is to generate positive instances only, using recurrences to combine positive instances to generate a "larger" positive instance. We call such a mode of dynamic programming execution *positive-instance driven* or *PID* for short. One goal of this paper is to demonstrate that PID is not simply a low-level implementation strategy but can be a paradigm of algorithm design for some problems.

The decision problem we consider is that of deciding, given graph G and positive integer k, if the treewidth of G is at most k. This graph parameter was introduced by Robertson and Seymour [17] and has had a tremendous impact on graph theory and on the design of graph algorithms (see, for example, a survey [7]). The treewidth problem is NP-complete [1] but fixed-parameter tractable: it has an $f(k)n^{O(1)}$ time algorithm for some fixed function f(k) as implied by the graph minor theorem of Robertson and Seymour [18], and an explicit O(f(k)n) time algorithm was given by Bodlaender [3]. A classical dynamic programming algorithm due to Arnborg, Corneil, and Proskurowsky (ACP algorithm) [1] runs in $n^{k+O(1)}$ time. Bouchitté and Todinca [9] developed a more refined dynamic programming algorithm (BT algorithm) based on the notions of minimal separators and potential maximal cliques, which lead to algorithms running in $O(1.7549^n)$ time or in $O(n^5\binom{\lceil (2n+k+8)/3\rceil}{k+2})$ time [11, 12]. Another important approach to treewidth computation is based on the perfect elimination order (PEO) of minimal chordal completions of the given graph. PEO-based dynamic programming algorithms run in $O^*(2^n)$ time with exponential space and in $O^*(4^n)$ time with polynomial space [4], where $O^*(f(n))$ means $O(n^c f(n))$ for some constant c.

There has been a considerable amount of effort on implementing treewidth algorithms to be used in practice and, prior to this work, the most successful implementations for exact treewidth computation are all based on PEO. The authors of [4] implemented the $O^*(2^n)$ time dynamic programming algorithm and experimented on its performance, showing that it works well for small instances. For larger instances, PEO-based branch-and-bound algorithms are known to work well in practice [13]. Recent proposals for reducing treewidth computation to SAT solving are also based on PEO [19,2]. From the PID perspective, this situation is somewhat surprising, since it can be shown that each positive subproblem instance in the PEO-based dynamic programming scheme corresponds to a combination of an indefinite number of positive subproblem instances in the ACP algorithm, and hence the number of positive subproblem instances can be exponentially larger than that in the ACP algorithm. Indeed, a PID variant of the ACP algorithm was implemented by the present author and has won the first place in the exact treewidth track of PACE 2016 [10], a competition on algorithm implementations, outperforming other submissions based on PEO. Given this success, a natural next step is to design a PID variant of the BT algorithm, which is tackled in this paper.

The resulting algorithm performs extremely well, as reported in Section 8. It is tested on DIMACS graph-coloring instances [14], which have been used in the literature on treewidth computation as standard benchmark instances [13,5,15,19,4,2]. Our implementation of the algorithm solves all the instances that have been previously solved (that is, with matching upper and lower bounds known) within 10 seconds per instance on a typical desktop computer and solves 13 out of the 42 previously unsolved instances. For nearly half of the instances which it leaves unsolved, it significantly reduces the gap between the lower and upper bounds. It is interesting to note that this is done by improving the lower bound. Since the number of positive subproblem instances are much smaller when k < tw(G) than when k = tw(G), the PID approach is particularly good at establishing strong lower bounds.

We also adopt the notion of safe separators due to Bodlaender and Koster [5] in our preprocessing and design a new heuristic algorithm for detecting safe separators. With this

preprocessing, our implementation also solves all of the 100 public instances posed by PACE 2017 [16], the successor of PACE 2016. It should be noted that these test instances of PACE 2017 are much harder than those of PACE 2016: the winning implementation of PACE 2016 mentioned above, which solved 199 of the 200 instances therein, solves only 62 of these 100 instances of PACE 2017 in the given time of 30 minutes per instance.

Adapting the BT algorithm to work in PID mode has turned out non-trivial. Each subproblem instance in the BT algorithm for given graph G and positive integer k takes the form of a connected set C of G such that $N_G(C)$, the open neighborhood of C in G, is a minimal separator of G with cardinality at most k. For each such C, we ask if C is feasible, in the sense that there is a tree decomposition of the subgraph of G induced by $C \cup N_G(C)$ of width at most k that has a bag containing $N_G(C)$ (see Section 2 for the definition of a tree decomposition of a graph). The difficulty of making the BT algorithm PID comes from the fact that the recurrence for deciding if C is feasible may involve an indefinite number of connected sets C' such that $C' \subset C$. Thus, even if the number of positive instances is small, there is a possibility that the running time is exponential in that number. We approach this issue by introducing an auxiliary structure we call O-blocks (see Section 3) and formulate a recurrences that are binary: a combination of a feasible connected set and a feasible O-block may yield either a larger feasible connected set or a larger feasible O-block. Due to this binary recurrence, we obtain an upper bound on the running time of our algorithm which is sensitive to the number of subproblem instances (Observation 1 in Section 5). To support the significance of such a bound, we perform an experimental analysis which shows the existence of huge gaps between the actual number of combinatorial objects corresponding to subproblems and the known theoretical upper bounds.

The rest of this paper is organized as follows. In Section 2, we introduce notation, define basic concepts and review facts in the literature. In Section 3, we precisely define the subproblems in our dynamic programming algorithm and formulate recurrences. We describe our algorithm and prove its correctness in Section 4 and then analyze its running time in Section 5. In Section 6, we describe our experimental analysis. In Section 7, we describe some implementation details. Finally, in Section 8, we give details of the performance results sketched above.

2 Preliminaries

In this paper, all graphs are simple, that is, without self loops or parallel edges. Let G be a graph. We denote by V(G) the vertex set of G and by E(G) the edge set of G. For each $v \in V(G)$, $N_G(v)$ denote the set of neighbors of v in G: $N_G(v) = \{u \in V(G) \mid \{u,v\} \in E(G).$ For $U \subseteq V(G)$, the *open neighborhood of U in G*, denoted by $N_G(U)$, is the set of vertices adjacent to some vertex in U but not belonging to U itself: $N_G(U) = (\bigcup_{v \in U} N_G(v)) \setminus U$. The *closed neighborhood of U in G*, denoted by $N_G[U]$, is defined by $N_G[U] = U \cup N_G(U)$. We also write $N_G[v]$ for $N_G[\{v\}] = N_G(v) \cup \{v\}$. We denote by G[U] the subgraph of G induced by U: V(G[U]) = U and $E(G[U]) = \{\{u,v\} \in E(G) \mid u,v \in U\}$. In the above notation, as well as in the notation further introduced below, we will often drop the subscript G when the graph is clear from the context.

We say that vertex set $C \subseteq V(G)$ is *connected in G* if, for every $u, v \in C$, there is a path in G[C] between u and v. It is a *connected component* of G if it is connected and is inclusionwise maximal subject to this condition. A vertex set G in G is a *component associated with* $S \subseteq G$, if G is a connected component of $G[V(G) \setminus S]$. For each $G \subseteq V(G)$, we denote by $\mathscr{C}_G(S)$ the set of all components associated with G. A vertex set $G \subseteq V(G)$ is a *separator* of

G if $|\mathscr{C}_G(S)| > \mathscr{C}_G(\emptyset)|$, that is, if its removal increases the number of connected components of G. A component C associated with separator S of G is a *full component* if $N_G(C) = S$. A separator S is a *minimal separator* if there are at least two full components associated with S. This term is justified by this fact: if S is a minimal separator and A, B vertices belonging to two distinct full components associated with S, then for every proper subset S' of S, A and B belong to the same component associated with S'; S is a minimal set of vertices that separates B from B. A B lock is a pair B is a separator and B is a component associated with S'; it is a *full block* if C is a full component, that is, S = N(C).

Graph H is *chordal* if every induced cycle of H has length exactly three. H is a *minimal* chordal completion of G if it is chordal, V(H) = V(G), $E(G) \subseteq E(H)$, and E(H) is minimal subject to these conditions. A vertex set $\Omega \subseteq V(G)$ is a *potential maximal* clique of G, if Ω is a clique in some minimal chordal completion of G.

A tree-decomposition of G is a pair (T, \mathcal{X}) where T is a tree and \mathcal{X} is a family $\{X_i\}_{i\in V(T)}$ of vertex sets of G such that the following three conditions are satisfied. We call members of V(T) nodes of T and each X_i the bag at node i.

- 1. $\bigcup_{i \in V(T)} X_i = V(G)$.
- 2. For each edge $\{u,v\} \in E(G)$, there is some $i \in V(T)$ such that $u,v \in X_i$.
- 3. The set of nodes $I_v = \{i \in V(T) \mid v \in X_i\}$ of V(T) induces a connected subtree of T.

The *width* of this tree-decomposition is $\max_{i \in V(T)} |X_i| - 1$. The *treewidth* of G, denoted by $\operatorname{tw}(G)$ is the minimum width of all tree-decompositions of G. We may assume that the bags X_i and X_j are distinct from each other for $i \neq j$ and, under this assumption, we will often regard a tree-decomposition as a tree T in which each node is a bag.

We call a tree-decomposition T of G canonical if each bag of T is a potential maximal clique of G and, for every pair X, Y of adjacent bags in T, $X \cap Y$ is a minimal separator of G. The following fact is well-known. It easily follows, for example, from Proposition 2.4 in [8].

Lemma 1 Let G be an arbitrary graph. There is a tree-decomposition T of G of width tw(G) that is canonical.

The following local characterization of a potential maximal clique is crucial. We say that a vertex set $S \subseteq V(G)$ is *cliquish* in G if, for every pair of distinct vertices u and v in S, either u and v are adjacent to each other or there is some $C \in \mathscr{C}(S)$ such that $u, v \in N(C)$. In other words, S is cliquish if completing N(C) for every $C \in \mathscr{C}(S)$ into a clique makes S a clique.

Lemma 2 (Theorem 3.15 in [8]) A separator S of G is a potential maximal clique of G if and only if (1) S has no full-component associated with it and (2) S is cliquish.

It is also shown in [8] that if Ω is a potential maximal clique of G and S is a minimal separator contained in Ω , then there is a unique component C_S associated with S that contains $\Omega \setminus S$. We need an explicit way of forming C_S from Ω and S.

Let $K \subseteq V(G)$ be an arbitrary vertex set and S an arbitrary proper subset of K. We say that a component $C \in \mathcal{C}(K)$ is *confined to* S if $N(C) \subseteq S$; otherwise it is *unconfined to* S. Let unconf(S,K) denote the set of components associated with K that are unconfined to S. Define the crib of S with respect to K, denoted by crib(S,K), to be $(K \setminus S) \cup \bigcup_{C \in unconf(S,K)} C$: it is the union of $K \setminus S$ and all those components associated with K that have neighborhoods intersecting $K \setminus S$.

The following lemma relies only on the second property of potential maximal cliques, namely that they are cliquish, and will be applied not only to potential maximal cliques but also to separators with full components, which are trivially cliquish.

Lemma 3 Let $K \subseteq V(G)$ be a cliquish vertex set. Let S be an arbitrary proper subset of K. Then, crib(S,K) is a full component associated with S.

Proof Let $C = \operatorname{crib}(S,K)$. We first show that G[C] is connected. Suppose $K \setminus S$ has two distinct vertices u and v. Since K is cliquish, either u and v are adjacent to each other or there is some component $C' \in \mathscr{C}(K)$ such that $u,v \in N(C')$. In the latter case, as C' is unconfined to S, we have $C' \subseteq C$. Therefore, u and v belong to the same connected component of G[C]. As this applies to every pair of vertices in $K \setminus S$, $K \setminus S$ is contained in a single connected component of G[C]. Moreover, each component $C' \in \mathscr{C}(K)$ contained in C is unconfined to C, by the definition of $\operatorname{crib}(S,K)$, and hence has a neighbor in C. Therefore, we conclude that C is connected. Each vertex C not in C belongs to some component in C that is confined to C and hence does not have a neighbor in C. Therefore, C is a component associated with C.

To see that C is a full component, let $u \in S$ and $v \in K \setminus S$ be arbitrary. Since K is cliquish, either u and v are adjacent to each other or there is some $C' \in \mathcal{C}(K)$ such that $u, v \in N(C')$. As such C' is unconfined to S in the latter case, we conclude that $u \in N(C)$ in either case. Since this holds for arbitrary $u \in S$, we conclude that C is a full component associated with S.

Remark 1 As $\operatorname{crib}(S,K)$ contains $K \setminus S$, it is clear that it is the only component associated with S that intersects K. Therefore, the above mentioned assertion on potential maximal cliques is a corollary to this Lemma.

3 Recurrences on oriented minimal separators

In this section, we fix graph G and positive integer k that are given in the problem instance: we are to decide if the treewidth of G is at most k. We assume that G is connected.

For connected set $C \subseteq V(G)$, we denote by $G\langle C \rangle$ the graph obtained from G[N[C]] by completing N(C) into a clique: $V(G\langle C \rangle) = N[C]$ and $E(G\langle C \rangle) = E(G[N[C]]) \cup \{\{u,v\} \mid u,v \in N(C), u \neq v\}$. We say C is *feasible* if $\operatorname{tw}(G\langle C \rangle) \leq k$. Equivalently, C is feasible if G[N[C]] has a tree-decomposition of width k or smaller that has a bag containing N(C).

Let us first review the BT algorithm [8] adapting it to our decision problem. We first list all minimum separators of cardinality k or smaller and all potential maximal cliques of cardinality k+1 or smaller. Then, for each pair of a potential maximal clique Ω and a minimal separator S such that $S \subset \Omega$, place a link from S to Ω . To understand the difficulty of formulating a PID variant of the algorithm, it is important to note that the pair (Ω, S) to be linked is easy to find from the side of Ω , but not the other way round. Then, we scan the full blocks (N(C), C) of minimal separators in the increasing order of |C| to decide if C is feasible, using the following recurrence: C is feasible if and only if there is some potential maximal clique Ω such that $N(C) \subset \Omega$, $C = \mathrm{crib}(N(C), \Omega)$, and every component $D \in \mathrm{unconf}(N(C), \Omega)$ is feasible. Finally, we have $\mathrm{tw}(G) \leq k$ if and only if there is a potential maximal clique Ω with $|\Omega| \leq k+1$ such that every component associated with Ω is feasible.

To facilitate the PID construction, we orient minimal separators as follows. We assume a total order < on V(G). For each vertex set $U \subseteq V(G)$, the *minimum element* of U, denoted by $\min(U)$, is the smallest element of U under <. For vertex sets U and W, we say U precedes W and write $U \prec W$ if $\min(U) < \min(W)$.

We say that a connected set C is *inbound* if there is some full block associated with N(C) that precedes C; otherwise, it is *outbound*. Observe that if C is inbound then N(C) is

a minimal separator, since N(C) has another full component associated with it and, contrapositively, if N(C) is not a minimal separator then C is necessarily outbound. We say a full block (N(C), C) is *inbound* (outbound) if C is inbound (outbound, respectively).

Lemma 4 Let K be a cliquish vertex set and let A_1, A_2 be two components associated with K. Suppose that A_1 and A_2 are outbound. Then, either $N(A_1) \subseteq N(A_2)$ or $N(A_2) \subseteq N(A_1)$.

Proof Let K, A_1 , and A_2 be as above and suppose neither of $N(A_1)$ and $N(A_2)$ is a subset of the other. For i = 1, 2, let $C_i = \operatorname{crib}(N(A_i), K)$. Since $N(A_2) \setminus N(A_1)$ is non-empty and contained in $K \setminus N(A_1)$, A_2 is contained in C_1 . We have $A_1 \prec C_1$ as A_1 is outbound and hence $A_1 \prec A_2$. A contradiction, since similarly we have $A_2 \prec A_1$.

Let K be a cliquish vertex set. Based on the above lemma, we define the *outlet* of K, denoted by $\operatorname{outlet}(K)$, as follows. If no non-full component associated with K is outbound, then we let $\operatorname{outlet}(K) = \emptyset$. Otherwise, $\operatorname{outlet}(K) = N(A)$, where A is a non-full component associated with K that is outbound, chosen so that N(A) is maximal. We define $\operatorname{support}(K) = \operatorname{unconf}(\operatorname{outlet}(K), K)$, the set of components associated with K that are not confined to $\operatorname{outlet}(K)$. By Lemma 4, every member of $\operatorname{support}(K)$ is inbound.

We call a full block (N(C), C) an *I-block* if C is inbound and $|N(C)| \le k$. We call it an O-block if C is outbound and $|N(C)| \le k$.

We say that an I-block (N(C), C) is *feasible* if C is feasible. We say that an O-block (N(A), A) is feasible if $N(A) = \bigcup_{C \in \mathscr{C}} N(C)$ for some set \mathscr{C} of feasible inbound components. Note that this definition of feasibility of an O-block is somewhat weak in the sense that we do not require every inbound component associated with N(A) to be feasible.

We say that a potential maximal clique Ω is *feasible* if $|\Omega| \le k+1$ and every $C \in \text{support}(\Omega)$ is feasible.

In order to formulate mutual recurrences among feasible I-blocks, O-blocks, and potential maximal cliques, we need the following auxiliary notion of *buildable* potential maximal cliques.

Let Ω be a potential maximal clique with $|\Omega| \le k+1$. For each $C \in \operatorname{support}(\Omega)$, block (N(C), C) is an I-block, since C is inbound as observed above and we have $|N(C)| \le k$ by our assumption that $|\Omega| \le k+1$. We say that Ω is *buildable* if $|\Omega| \le k+1$ and either

- 1. $\Omega = N[v]$ for some $v \in V(G)$,
- 2. there is some subset $\mathscr C$ of support(Ω) such that $\Omega = \bigcup_{D \in \mathscr C} N(D)$ and every member of $\mathscr C$ is feasible, or
- 3. $\Omega = N(A) \cup (N(v) \cap A)$ for some feasible O-block (N(A), A) and a vertex $v \in N(A)$.

It will turn out that every feasible potential maximal clique is buildable (Lemma 9).

Lemma 5 We have $tw(G) \le k$ if and only if G has a feasible potential maximal clique Ω with $outlet(\Omega) = \emptyset$.

Proof Suppose first that G has a feasible potential maximal clique Ω with $\operatorname{outlet}(\Omega) = \emptyset$. Note that $\operatorname{support}(\Omega) = \mathscr{C}(\Omega)$, as every $C \in \mathscr{C}(\Omega)$ is unconfined to an empty set. For each component $C \in \operatorname{support}(\Omega)$, let T_C be the tree-decomposition of $G\langle C \rangle$ of width k or smaller, which exists since C is feasible by the definition of a feasible potential maximal clique. Let X_C be a bag of T_C such that $N(C) \subseteq X_C$. Combine these tree-decompositions into a tree T by adding bag Ω and letting each X_C in T_C be adjacent to Ω . That T satisfies the first two conditions for tree decomposition is trivial. The third condition is also satisfied, since, if a vertex v appears in N[C] for two or more members C in support (Ω) , then v appears in X_C

for each such C and in Ω . Therefore, T is a tree decomposition of G of width k or smaller and hence $\mathrm{tw}(G) < k$.

For the converse, suppose the treewidth of G is k or smaller. Let T be a canonical treedecomposition of G of width k or smaller: each bag of T is a potential maximal clique and the intersection of each pair of adjacent bags of T is a minimal separator. Orient each edge of T as follows. Let X and Y be adjacent bags in T and let $S = X \cap Y$. Let C be the outbound full component associated with the minimal separator S. Then, C intersects exactly one of X and Y. If C intersects X then we orient the edge between X and Y from Y to X; otherwise from X to Y. Since T is a tree, the resulting directed tree has a sink X_0 . Then, each component C associated with X_0 is inbound and hence outlet(X_0) = \emptyset . We show that each such C is moreover feasible. Indeed, the required tree-decomposition of G(C) may be obtained from T by taking intersection of every bag with N[C]: the resulting tree is a tree-decomposition of G(N(C)) and contains the bag $X_0 \cap N[C] \supseteq N(C)$. The width of the tree-decomposition is not greater than that of T and hence is K or smaller. Therefore, I-block K(N(C), C) for each component C associated with K_0 is feasible and hence the potential maximal clique K_0 is feasible.

Lemma 6 Let C be a connected set of G such that N(C) is a minimal separator. Let Ω be a potential maximal clique of G(C). Then, Ω is a potential maximal clique of G.

Proof For each component D associated with N(C), let H_D be a minimal chordal completion of $G\langle C\rangle$. In particular, choose H_C so that Ω is a clique in H_C . Let H be the union of these graphs: V(H) = V(G) and $E(H) = \bigcup_{D \in \mathscr{C}(N(C))} E(H_D)$. It is clear that H is chordal. Let H' be a minimal chordal completion of G contained in H. It is well-known that every minimal separator is a clique in every chordal completion and hence N(C) is a clique in H'. Therefore, the minimality of H_D for each D implies that H' = H. As Ω is a clique in H_C , it is a clique in H and hence is a potential maximal clique of G.

The following is our oriented version of the recurrence in the BT algorithm described in the beginning of this section.

Lemma 7 An I-block (N(C),C) is feasible if and only if there is some feasible potential maximal clique Ω with $\mathrm{outlet}(\Omega)=N(C)$ and $\bigcup_{D\in \mathrm{support}(\Omega)}D=C$.

Proof Suppose first that there is a feasible potential maximal clique Ω as in the lemma. For each component $D \in \operatorname{support}(\Omega)$, let T_D be a tree-decomposition of $G\langle D \rangle$ of width k or smaller and X_D be a bag in T_D containing N(D). Combine these tree-decompositions T_D , $D \in \operatorname{support}(\Omega)$, into a tree T by adding bag Ω and let it be adjacent to X_D for each $D \in \operatorname{support}(\Omega)$. We confirm that T is a tree-decomposition of G[N[C]]. Every vertex $v \in N[C]$ appears in some bag of T since C is the union of D for all $D \in \operatorname{support}(\Omega)$ and the bag Ω contains N(C). Every edge of G[N[C]] appears in some bag of T for the same reason. The third condition for T being a tree decomposition is also satisfied, since, if a vertex v appears in N[D] for two or more members D in support D0, then D1 appears in D2 for each such D3 and in D3. Therefore, D3 is a tree decomposition of D4 width D5 or smaller and hence the bag D6 in D7 contains D8. The each such D9 for each such D9 and in D9 contains D9 for each such D9 and in D9 for contains D9. The each such D9 for each D9 for each such D9 for each such D9 for each D9 fo

For the converse, suppose that I-block (N(C), C) is feasible. Let T be a canonical tree-decomposition of $G\langle C\rangle$ of width k or smaller. Orient the edges of T as in the proof of Lemma 5: orient the edge from X to Y if and only if Y intersects the outbound full component associated with $X \cap Y$. We need to stress here that the notion of outbound components used in this orientation is with respect to the entire graph G and not with respect to $G\langle C\rangle$, the

graph of which T is a tree-decomposition. As N(C) is a clique in $G\langle C \rangle$, T contains a bag that contains N(C). In the subtree of T induced by those bags containing N(C), let X_0 be a sink with respect to the above orientation. As T is canonical, X_0 is a potential maximal clique of $G\langle C \rangle$ and hence of G by Lemma 6. We show below that X_0 is feasible.

Let A be the outbound full component associated with N(C). As $N(C) \subseteq X_0$ and $A \cap N[C] = \emptyset$, A is a component associated with X_0 . We claim that $N(C) = \text{outlet}(X_0)$. Suppose otherwise that there is some outbound component A' associated with X_0 such that N(C) is a proper subset of N(A'). Then, as A' is not confined to N(C), $C = \text{crib}(N(C), X_0)$ contains A'. Therefore, there is some bag X adjacent to X_0 in T such that $X \cap A' \neq \emptyset$. Since N(C) is a minimal separator that separates A from A', X must contain N(C). But, since A' is an outbound component associated with X_0 , the edge between X_0 and X is oriented from X_0 to X. This contradicts the choice of X_0 and we conclude that $N(C) = \text{outlet}(X_0)$.

It remains to verify that each $D \in \operatorname{support}(X_0)$ is feasible. This is true since the tree of bags obtained from T by intersecting each bag with N[D] is a tree-decomposition of $G\langle D\rangle$ required for the feasibility of D.

Lemma 8 *Let K be a cliquish vertex set,* \mathscr{C} *a non-empty subset of* support(K), and $S = \bigcup_{C \in \mathscr{C}} N(C)$. *If S is a proper subset of K then* $\operatorname{crib}(S,K)$ *is outbound.*

Proof Let K, \mathscr{C} and S be as in the lemma. Since K is cliquish, $\mathrm{crib}(S,K)$ is a full component associated with S that contains $K \setminus S$, by Lemma 3. To show that it is outbound, it suffices to show that no other full component associated with S is outbound. Let A be an arbitrary full component associated with S that is distinct from $\mathrm{crib}(S,K)$. As S does not intersect S, it is a component associated with S. Let S be an arbitrary member of S. Then, S is confined to S by the definition of S. On the other hand S is not confined to outlet(S) since S is not a subset of S outlet(S). A cannot be outbound, since it would imply that S = S(S) outlet(S). Therefore, S is inbound and, since this holds for every full component associated with S other than S0, S1, S2, S3, S3, S4 is outbound. S5

The following lemma is crucial for our PID result: the algorithm described in the next section generates all buildable potential maximal cliques and we need to guarantee all feasible maximal cliques to be among them.

Lemma 9 Let Ω be a feasible potential maximal clique. Then, Ω is buildable.

Proof Let $S = \bigcup_{C \in \text{support}(\Omega)} N(C)$.

Suppose first that $S \cup \operatorname{outlet}(\Omega) \neq \Omega$ and let v be an arbitrary member of $\Omega \setminus (S \cup \operatorname{outlet}(\Omega))$. Since Ω is cliquish and v is not in N(C) for any component C associated with Ω , v is adjacent to every other vertex in Ω . Therefore, $\Omega \subseteq N[v]$. Let C be an arbitrary component associated with Ω . If C is confined to $\operatorname{outlet}(\Omega)$ then $v \notin N(C)$ since $v \notin \operatorname{outlet}(\Omega)$. Otherwise, $C \in \operatorname{support}(\Omega)$ and hence $v \notin N(C)$ as $v \notin S$. Therefore, $N(v) \setminus \Omega$ is empty and hence we have $\Omega = N[v]$. Thus, Ω is buildable, the first case of buildability.

Suppose next that $S \cup \operatorname{outlet}(\Omega) = \Omega$. We have two cases to consider: $S = \Omega$ and $S \neq \Omega$. Consider the case where $S = \Omega$. Let \mathscr{C}_0 be an arbitrary minimal subset of support(Ω) such that $\bigcup_{C \in \mathscr{C}_0} N(C) = \Omega$. Since Ω does not have a full component associated with it, \mathscr{C}_0 has at least two members. Let C_0 be an arbitrary member of \mathscr{C}_0 and let $\mathscr{C}_1 = \mathscr{C}_0 \setminus \{C_0\}$. From the minimality of \mathscr{C}_0 , $S_1 = \bigcup_{C \in \mathscr{C}_1} N(C)$ is a proper subset of Ω . By Lemmas 3 and 8, $A_1 = \operatorname{crib}(S_1, \Omega)$ is a full component associated with S_1 and is outbound. Therefore, (S_1, A_1) is an O-block and is feasible since every member of $\mathscr{C}_1 \subseteq \operatorname{support}(\Omega)$ is feasible as potential maximal clique Ω is feasible. Thus, the second case in the definition of feasible potential maximal cliques applies.

Finally, suppose that $S \neq \Omega$. Let $A = \operatorname{crib}(S,\Omega)$. Then, A is a full component associated with S and is outbound, by Lemmas 3 and 8. Since $S = \bigcup_{C \in \operatorname{support}(\Omega)} N(C)$ and Ω is feasible, the O-block (S,A) is feasible. Let x be an arbitrary vertex in $\Omega \setminus S$. Since we are assuming that $S \cup \operatorname{outlet}(\Omega) = \Omega$ we have $x \in \operatorname{outlet}(\Omega) \setminus S$. Let v be an arbitrary vertex in $\Omega \setminus \operatorname{outlet}(\Omega)$. Observe that there is no component C associated with Ω such that N(C) contains both x and v: $x \notin N(C)$ for every $C \in \operatorname{support}(\Omega)$ and $v \notin N(C)$ for every C that is confined to C outlet C. Since C is cliquish, it follows that C and C are adjacent to each other. Therefore, we have C and C is cliquish, it follows that C and C is disjoint from C0, since every component C0 associated with C2 such that C2 is disjoint from C3, since every component C4 associated with C5 such that C5 is not confined to outlet C6 and hence contained in C6. Therefore, we have C6 and hence C7 is not confined to a full the definition of buildable potential maximal cliques applies.

4 Algorithm

Given graph G and positive integer k, our algorithm generates all I-blocks, O-blocks, and potential maximal cliques that are feasible. In the algorithm description below, the following variables, with suffixes, are used: $\mathscr I$ for listing feasible I-blocks, $\mathscr O$ for feasible O-blocks, $\mathscr P$ for buildable potential maximal cliques, and $\mathscr S$ for feasible potential maximal cliques. We note that each member of $\mathscr I$ and $\mathscr O$ is actually the component part of an I- or O-block.

Algorithm PID-BT

Input: Graph G and positive integer k

Output: "YES" if $tw(G) \le k$; "NO" otherwise

Procedure:

- 1. Let $\mathscr{I}_0 = \emptyset$ and $\mathscr{O}_0 = \emptyset$.
- 2. Initialize \mathcal{P}_0 and \mathcal{S}_0 to \emptyset .
- 3. Set j = 0.
- 4. For each $v \in V(G)$, if N[v] is a potential maximal clique with $|N[v]| \le k+1$ then add N[v] to \mathcal{P}_0 and if, moreover, support $(N[v]) = \emptyset$ then do the following.
 - (a) Add N[v] to \mathcal{S}_0 .
 - (b) If $\operatorname{outlet}(N[v]) \neq \emptyset$ then let $C = \operatorname{crib}(\operatorname{outlet}(N[v]), N[v])$ and, provided that $C \neq C_h$ for $1 \leq h \leq j$, increment j and let $C_j = C$.
- 5. Set i = 0.
- 6. Repeat the following and stop repetition when *j* is not incremented during the iteration step.
 - (a) While i < j, do the following.
 - i. Increment i and let \mathscr{I}_i be $\mathscr{I}_{i-1} \cup \{C_i\}$.
 - ii. Initialize \mathcal{O}_i to \mathcal{O}_{i-1} , \mathcal{P}_i to \mathcal{P}_{i-1} , and \mathcal{S}_i to \mathcal{S}_{i-1} .
 - iii. For each $B \in \mathcal{O}_{i-1}$ such that $C_i \subseteq B$ and $|N(C_i) \cup N(B)| \le k+1$, let $K = N(C_i) \cup N(B)$ and do the following.
 - A. If K is a potential maximal clique, then add K to \mathcal{P}_i .
 - B. If $|K| \le k$ and there is a full component A associated with K (which is unique), then add A to \mathcal{O}_i .
 - iv. Let A be the full component associated with $N(C_i)$ and add A to \mathcal{O}_i .
 - v. For each $A \in \mathcal{O}_i \setminus \mathcal{O}_{i-1}$ and $v \in N(A)$, let $K = N(A) \cup (n(v) \cap A)$ and if $|K| \le k+1$ and K is a potential maximal clique then add K to \mathcal{P}_i .

vi. For each $K \in \mathscr{P}_i \setminus \mathscr{S}_{i-1}$, if $\operatorname{support}(K) \subseteq \mathscr{I}_i$ then add K to \mathscr{S}_i and do the following: if $\operatorname{outlet}(K) \neq \emptyset$ then let $C = \operatorname{crib}(\operatorname{outlet}(K), K)$ and, provided that $C \neq C_h$ for $1 \leq h \leq j$, increment j and let $C_j = C$.

7. If there is some $K \in \mathcal{S}_j$ such that $\text{outlet}(K) = \emptyset$, then answer "YES"; otherwise, answer "NO".

Theorem 1 Algorithm PID-BT, given G and k, answers "YES" if and only if $tw(G) \le k$.

Proof We show that \mathcal{S}_J computed by the algorithm, where J denotes the final value of j, is exactly the set of feasible potential maximal cliques for the given G and k. The theorem then follows by Lemma 5.

In the following proof, \mathcal{O}_i , \mathcal{P}_i , and \mathcal{S}_i for each i stand for the final values of these program variables.

We first show by induction on i that the following conditions are satisfied.

- 1. For every $1 \le h \le i$, $(N(C_i), C_i)$ is a feasible I-block.
- 2. $\mathscr{I}_i = \{C_h \mid 1 \le h \le i\}.$
- 3. For every $A \in \mathcal{O}_i$, (N(A), A) is a feasible O-block.
- 4. Every $K \in \mathcal{P}_i$ is a buildable potential maximal clique.
- 5. Every $K \in \mathcal{S}_i$ is a feasible potential maximal clique.

Consider the base case i=0. Condition 1 vacantly holds. Conditions 2 and 3 also hold since $\mathscr{I}_0=\mathscr{O}_0=\emptyset$. Condition 4 holds: N[v] is confirmed to be a potential maximal clique before it is added to \mathscr{P}_0 and is buildable by the definition of buildability (case 1). Condition 5 holds since support(N[v]) = \emptyset implies that the potential maximal clique N[v] is feasible.

Suppose i > 0 and that the above conditions are satisfied for smaller values of i.

- 1. When C_i is defined, there is some i' < i and $K \in \mathcal{S}_{i'}$ such that $\operatorname{outlet}(K) \neq \emptyset$ and $C_i = \operatorname{crib}(\operatorname{outlet}(K), K)$. By the induction hypothesis, K is a feasible potential maximal clique and hence, by Lemma 7, $(N(C_i), C_i)$ is a feasible I-block.
- 2. As $\mathscr{I}_{i-1} = \{C_h \mid 1 \le h \le i-1\}$ and $\mathscr{I}_i = \mathscr{I}_{i-1} \cup \{C_i\}, \mathscr{I}_i = \{C_h \mid 1 \le h \le i\}$ holds.
- 3. Let $A \in \mathcal{O}_i \setminus \mathcal{O}_{i-1}$. Then there is some $B \in \mathcal{O}_{i-1}$ such that A is outbound, $|N(A)| \leq k$, and $N(A) = N(C_i) \cup N(B)$. From the first two conditions, (N(A), A) is an O-block. By the induction hypothesis, (N(B), B) is a feasible O-block and hence $N(B) = \bigcup_{D \in \mathscr{C}} N(D)$ for some set \mathscr{C} of feasible inbound components. As C_i is feasible by 1 above and $N(A) = \bigcup_{D \in \mathscr{C} \cup \{C_i\}} N(D)$, O-block (N(A), A) is feasible.
- 4. Let $K \in \mathscr{P}_i \setminus \mathscr{P}_{i-1}$. Then, K is added to \mathscr{P}_i either at step 6-(a)-iii-A or at step 6-(a)-v. Consider the first case, Then, $K = N(B) \cup N(C_i)$ where (N(B), B) is a feasible O-block and hence $N(B) = \bigcup_{D \in \mathscr{C}} N(D)$ for some set \mathscr{C} of feasible inbound components. As C_i is feasible, K satisfies all the conditions in the second case of the definition of buildable potential maximal cliques. Consider next the second case, K is obtained at step 6-(a)-v. Then, $K = N(A) \cup (n(v) \cap A)$, where (N(A), A) is a feasible O-block, and the third case in the definition of buildable potential maximal cliques applies.
- 5. Let $K \in \mathcal{S}_i \setminus \mathcal{S}_{i-1}$. Then, $K \in \mathcal{P}_i$ and is a buildable potential maximal clique by 4 above. The confirmed condition support $(K) \subseteq \mathcal{I}_i$ ensures that K is feasible, since every member of \mathcal{I}_i is feasible by 1 and 2 above.

We conclude that every member of \mathcal{S}_J is a feasible potential maximal clique.

In showing the converse, the following observation is crucial. Let (N(A), A) be a feasible O-block such that $N(A) = \bigcup_{C \in \mathscr{C}} N(C)$ for some set \mathscr{C} of feasible components and suppose $\mathscr{C} \subseteq \mathscr{I}_i$. Then, $A \in \mathscr{O}_i$. The proof is a straightforward induction on i.

The proof of the converse consists in showing the following by induction on m.

- 1. For each feasible I-block (N(C), C), with |C| = m, there is some i such that $C = C_i$.
- 2. For each feasible O-block (N(A),A) with |A| = |V(G)| m, there is some i such that $A \in \mathcal{O}_i$.
- 3. For each buildable potential maximal clique Ω such that $|\bigcup_{C \in \text{support}(\Omega)} C| = m$, there is some i such that $\Omega \in \mathcal{P}_i$.
- 4. For each feasible potential maximal clique Ω such that $|\bigcup_{C \in \text{support}(\Omega)} C| = m$, there is some i such that $\Omega \in \mathscr{S}_i$.

The base case m = 0 is vacantly true. Suppose m > 0 and the statements hold for smaller values of m.

- 1. Let (N(C), C) be a feasible I-block with |C| = m. Then, by Lemma 7, there is some feasible potential maximal clique Ω such that $N(C) = \operatorname{outlet}(\Omega)$ and $C = \operatorname{crib}(N(C), \Omega)$. We have $|\bigcup_{C \in \operatorname{support}(\Omega)} C| < m$, since this union is a subset of $C \setminus (\Omega \setminus N(C))$. Therefore, by the induction hypothesis, there is some i such that $\Omega \in \mathcal{S}_i$. Therefore, C is constructed as C_i either at step 4-(b) or at step 6-(a)-vi.
- 2. Let (N(A),A) be a feasible O-block with |A| = |V(G)| m. Let \mathscr{C} be a set of feasible components such that $N(A) = \bigcup_{C \in \mathscr{C}} N(C)$ and let C be an arbitrary member of \mathscr{C} . As C, A, and N(C) are pairwise disjoint, we have |C| < m. Therefore, there is some i_C such that $C_{i_C} = C$. Set $i = \max\{i_C \mid C \in \mathscr{C}\}$. Then, $\mathscr{C} \subseteq \mathscr{I}_i$ and hence $A \in \mathscr{O}_i$, by the observation above.
- 3. Let Ω be a buildable potential maximal clique with $|\bigcup_{C \in \text{support}(\Omega)} C| = m$. In the first case of the definition of buildability, Ω is added to \mathcal{P}_0 at step 4. In the second case, we have $\Omega = \bigcup_{C \in \mathscr{C}} N(C)$ for some $\mathscr{C} \subseteq \text{support}(\Omega)$ such that every member of \mathscr{C} is feasible. Choose \mathscr{C} to be minimal subject to these conditions. Let C be an arbitrary member of \mathscr{C} . As $|C| \leq m$, by the induction hypothesis and 1 above, there is some i_C such that $\mathscr{C} \subseteq \mathscr{I}_{i_C}$. Choose $C \in \mathscr{C}$ so that i_C is the largest and let the chosen be D. Let $\mathscr{C}' = \mathscr{C} \setminus \{D\}$ and let $S = \bigcup_{C \in \mathscr{C}'} N(C)$. By the minimality of \mathscr{C} , S is a proper subset of Ω . Therefore, $\operatorname{crib}(S,\Omega)$ is a full component associated with S and there is an outbound full component A associated with S. As all members of \mathscr{C}' is feasible and $|S| \leq k$, (S,A) is a feasible O-block. By the choice of D, we have $\mathscr{C}' \subseteq \mathscr{I}_{i_D-1}$ and hence $A \in \mathscr{O}_{i_D-1}$ by the observation above. At step 6-(a)-iii-A in the iteration for $i = i_D$, Ω is put into \mathscr{P}_{i_D} .
- 4. Let Ω be a feasible potential maximal clique with $|\bigcup_{C \in \text{support}(\Omega)} C| = m$. Then, by 3 above, there is some i_1 such that $\Omega \in \mathscr{P}_{i_1}$. Furthermore, as every member C of support(Ω) is feasible and $|C| \leq m$, there is some i_2 such that support(Ω) $\subseteq \mathscr{I}_{i_2}$, by 1 above. At step 7 in the iteration for $i = \max\{i_1, i_2\}$, Ω is put into \mathscr{S}_i .

We conclude that every feasible potential maximal clique is in \mathcal{S}_J . This completes the proof.

5 Running time analysis

The running time of our algorithm is stated in terms of the the number of positive subproblem instances. Given G and k > 0, let \mathscr{I}_G^k denote the set of feasible I-blocks and \mathscr{O}_G^k the set of feasible O-blocks.

Observation 1 Given G and k > 0, algorithm PID-BT runs in $O^*(|\mathscr{I}_G^k| \cdot |\mathscr{O}_G^k|)$ time.

Proof The number of iteration in step 6, where *i* is incremented each time, is $|\mathscr{I}_G^k|$. In each iteration step, every computation step may be charged to each element of \mathscr{O}_{i-1} and the total

number of steps charged to a single element of \mathcal{O}_{i-1} is $n^{O(1)}$. Since $|\mathcal{O}_{i-1}| \leq |\mathcal{O}_G^k|$, we have the claimed time bound.

The bound in this observation is incomparable to the previous bounds on non-PID versions of the BT algorithm, which run in $O^*(|\Pi_G|)$ time when Π_G , the set of potential maximal cliques in G, is given. In [12], in addition to a combinatorial bound of $|\Pi_G| = O(1.7549^n)$, it was shown that Π_G can be computed in $O^*(\Pi_G)$ time.

It should be emphasized, however, that it is not known whether the decision problem version of the treewidth problem with given k can be solved in $O^*(|\Pi_G^{k+1}|)$ time, where Π_G^k is the set of potential maximal cliques of cardinality at most k in G. The bottleneck here is the time to list all members of Π_G^{k+1} . Although a nontrivial upper bound on $|\Pi_G^{k+1}|$ in terms of n and k, together with a running time bound based on it, is given in [12], a huge gap between the actual value $|\Pi_G^{k+1}|$ and the upper bound is observed in practice, as shown in the next section. This is the gap that makes the bound in Observation 1 interesting.

6 Experimental analysis

To study the strength of the running time bound of Observation 1 from a practical view point, we have performed some experiments, in which we count the number of combinatorial objects involved in the treewidth computation. We first compare the actual number of relevant potential maximal cliques (that is, of cardinality at most k+1 where k is the treewidth) with the theoretical uppser bounds on that number: the naive bound of $\binom{n}{k+1}$ and an assymptotically stronger bound of $n(\binom{\lceil (2n+k+7)/3 \rceil}{k+2}) + \binom{\lceil (2n+k+4)/2 \rceil}{k+1})$ given in [12]. Table 1 shows the results on some random instances, where the number of vertices n is 20, 30, 40, or 50, the number of edges m is 2n, 3n, 4n or 5n, and the graph for each pair (n,m) is chosen uniformly at random from the set of all graphs with n vertices and m edges. Huge gaps between the actual number and the upper bounds are apparent.

Table 1 The numbers of relevant potential maximal cliques and their upper bounds

Since the running time bound in Observation 1 involves the quantity $|\mathcal{O}_G^k|$ which is not theoretically upper-bounded by a function of $|\Pi_G^{k+1}|$, the gaps observed in Table 1 alone may not be sufficient to support the importance of this running time bound. To address this issue, we have counted more combinatorial objects involved in our PID computation on the same graph instances: in addition to relevant potential maximal cliques counted above, all potential maximal cliques, relevant minimal separators, all minimal separators, feasible I-blocks, feasible O-blocks and feasible potential maximal cliques. Here, the input k to the decision problem is set to the treewidth of the graph.

Table 2 shows the result. We see that the number of feasible O-blocks is smaller than the number of relevant potential mmaximal cliques, as far as these instances are concerend. This, together with what we have observed in Table 1, provides an evidence that the running time bound of Observation 1 is more relevant from a practical point of view than the running time bounds of known theoretical algorithms.

We also see that the number of all potential maximal cliques grows much faster than the number of relevant potential maximal cliques. This shows the advantage of our algorithm which avoids generating all potential maximal cliques.

To summarize, our PID algorithm has advantages over the standard BT algorithms because the running time upper bounds of those algorithms are either in terms of a combinatorial *upper bound* on the number of relevant potential maximal cliques or in terms of the actual number of *all* potential maximal cliques: our experiments reveal huge gaps between the actual number of relevant potential maximal cliques and both of these quantities. Note that, if there is an efficient method of generating relevant potential maximal cliques, a non-PID version of the BT algorithm might outperform our PID version.

7 Implementation

In this section, we sketch two important ingredients of our implementation. Although both are crucial in obtaining the result reported in Section 8, our work on this part is preliminary and improvements are the subject of future research.

7.1 Data structures

The crucial elementary operation in our algorithm is the following. We have a set \mathscr{O} of feasible O-blocks obtained so far and, given a new feasible I-block (N(C), C), need to find all members (N(A), A) of \mathscr{O} such that $C \subseteq A$ and $|N(C) \cup N(A)| \le k+1$. As the experimental analysis in the previous section shows, there is only a few such A on average for the tested instances even though \mathscr{O} is usually huge. To support an efficient query processing, we introduce an abstract data structure we call a block sieve.

Let G be a graph and k a positive integer. A *block sieve* for graph G and width k is a data structure storing vertex sets of V(G) which supports the following operations.

 $\operatorname{store}(U)$: store vertex set U in in the block sieve. $\operatorname{supersets}(U)$: return the list of entries W stored in the block sieve such that $U\subseteq W$ and $|N(U)\cup N(W)|\leq k+1$.

Data structures for superset query have been studied [20]. The second condition above on the retrieved sets, however, appears to make this data structure new. For each $U \subseteq V(G)$, we define the *margin* of U to be k+1-|N(U)|. Our implementation of block sieves described below exploits an upper bound on the margins of vertex sets stored in the sieve.

We first describe how such block sieves with upper bounds on margins are used in our algorithm. Let \mathcal{O} be the current set of O-blocks. We use t block sieves $\mathcal{B}_1, \ldots, \mathcal{B}_t$, each \mathcal{B}_i having a predetermined upper bound m_i on the margins of the sets stored. We have $0 < m_1 < m_2 < \ldots < m_t = k$. We set $m_0 = 0$ for notational ease below. In our implementation, we choose roughly $t = \log_2 k$ and $m_i = 2^i$ for 0 < i < t. For each (N(A), A) in \mathcal{O} , A is stored in \mathcal{B}_i such that the margin k + 1 - |N(A)| is m_i or smaller but larger than m_{i-1} . When we are given an I-block (N(C), C) and are to list relevant blocks in \mathcal{O} , we query all of the t blocks with the operations supersets (C). These queries as a whole return the list of all vertex sets A such that $(N(A), A) \in \mathcal{O}$, $C \subseteq A$, and $|(N(A) \cup N(C))| \le k + 1$.

We implement a block sieve by a trie \mathscr{T} . The upper bound m on margin is not used in the construction of the sieve; it is used in the query time. In the following, we assume $V(G) = \{1, \ldots, n\}$ and, by an interval [i, j], $1 \le i \le j \le n$, we mean the set $\{v : i \le v \le j\}$ of vertices. Each non-leaf node p of \mathscr{T} is labelled with a non-empty interval $[s_p, f_p]$, such that $s_r = 0$ for the root r, $s_p = f_q + 1$ if p is a child of q, and $f_p = n$ if p is a parent of a leaf. Each edge (p,q) which connects node p and a child q of p, is labelled with a subset $S_{(p,q)}$ of the interval $[s_p, f_p]$. Thus, for each node p, the union of the labels of the edges along the path from the root to p is a subset of the interval $[1, s_p - 1]$, or [1, n] when p is a leaf, which we denote by S_p . The choice of interval $[s_p, f_p]$ for each node p is heuristic. It is chosen so that the number of descendants of p is not too large or too small. In our implementation, the interval size is adaptively chosen from 8, 16, 32, and 64.

Each leaf q of trie $\mathscr T$ represents a single set stored at this leaf, namely S_q as defined above. We denote by $S(\mathscr T)$ the set of all sets stored in $\mathscr T$. Then, for each node p of $\mathscr T$, the set of sets stored under p is $\{U \mid U \cap [1,p] = S_p\}$.

We now describe how a query is processed against this data structure. Suppose query U is given. The goal is to visit all leaves q such that $U \subseteq S_q$ and $|N(U) \cup N(S_q)| \le k+1$. This is done by a depth-first traversal of the trie \mathscr{T} . When we visit node p, we have the invariant that $U \cap [1, f_p] \subseteq S_p$, since otherwise no leaf in the subtree rooted at p stores a superset of U. Therefore, we descend from p to a child p' of p only if this invariant is maintained. Moreover, we keep track of the quantity $i(p,U) = |N(U) \cap S_p|$ in order to make further pruning of search possible. For each leaf q below p such that $U \subseteq S_q$, we have $i(q,U) \ge i(p,U)$. Combining this with eauality $|N(U) \setminus N(S_q)| = |N(U) \cap S_q| = i(q,U)$, we

have $|N(U) \cup N(S_q)| \ge |N(S_q)| + i(p,U)$. Since we know an upper bound m on the margin $k+1-|N(S_q)|$ of S_q , or lower bound k+1-m on $|N(S_q)|$, we may prune the search under node p if i(p,U) > m, since this inequality implies $|N(U) \cup N(S_q)| > k+1$ for every leaf q under p. When we reach a leaf q, we test if $|N(U) \cup N(S_q)| \le k+1$ indeed holds.

7.2 Safe separators

The notion of safe separators for treewidth was introduced by Bodlaender and Koster [5]: a separator S of G is safe if completing S into a clique does not change the treewidth of G. If we find a safe separator S then the problem of deciding tree width of G reduces to that of deciding the treewidth of $G\langle C \rangle$ for each component C associated with S. Preprocessing G into such independent subproblems is highly desirable whenever possible.

The above authors observed that a powerful sufficient condition for safeness can be formulated based on graph minors. A *labelled minor* of G is a graph obtained from G by zero or more applications of the following operations. (1) Edge contraction: choose an edge $\{u,v\}$, replace u and v by a single new vertex and let all neighbors of u and v be adjacent to this new vertex; name the new vertex as either u or v. (2) Vertex deletion: delete a vertex together with all incident edges. (3) Edge deletion.

Lemma 10 ([5]) A separator S of G is safe if, for every component C associated with S, $G[V(G) \setminus C]$ contains clique S as a labelled minor.

Call a separator *minor-safe* if it satisfies the sufficient condition for safeness stated in this lemma. Bodlaender and Koster [5] showed that if S is a minimal separator and is an almost clique (deleting some single vertex makes it a clique) then S is minor-safe and moreover that the set of all almost clique minimal separators can be found in $O(n^2m)$ time, where n is the number of vertices and m is the number of edges.

We aim at capturing as many minor-safe separators as possible, at the expense of theoretical running time bounds on the algorithm for finding them. Thus, in our approach, both the algorithm for generating candidate separators and the algorithm for deciding minor-safeness are heuristic. For candidate generation, we use greedy heuristic for treewidth such as minfill and min-degree: the separators in the resulting tree-decomposition are all candidates for safe separators.

When we apply our heuristic decision algorithm for minor-safeness to candidate separator *S*, one of the following occurs.

- 1. The algorithm answers "YES". In this case, a required labelled clique minor has been found for every component associated *S* and hence *S* is minor-safe.
- 2. The algorithm answers "DON'T KNOW". In this case, the algorithm has failed to find a labelled clique minor for at least one component, and hence it is not known if *S* is minor-safe or not.
- 3. The algorithm aborts, after reaching the prescribed number of execution steps.

Our heuristic decision algorithm works in two phases. Let S be a separator, C a component associated with S, and $R = V(G) \setminus (S \cup C)$. In the first phase, we contract edges in R and obtain a graph B on vertex set $S \cup R'$, where each vertex of R' is a contraction of some vertex set of R and B has no edge between vertices in R'. For each pair u, v of distinct vertices in S, let N(u, v) denote the common neighbors of u and v in graph u. The contractions are performed with the goal of making $|N(u, v) \cap R'|$ large for each missing edge $\{u, v\}$ in S. In the second phase, for each missing edge $\{u, v\}$, we choose a common neighbor

 $w \in N(u,v) \cap R'$ and contract either $\{u,w\}$ or $\{v,w\}$. The choice of the next missing edge to be processed and the choice of the common neighbor are done as follows. Suppose the contractions in the second phase are done for some missing edges in S. For each missing edge $\{u,v\}$ not yet "processed", let N'(u,v) be the set of common neighbors of u and v that are not yet contracted with any vertex in S. We choose $\{u,v\}$ with the smallest $|N'(u,v) \cap R'|$ to be processed next. Tie-breaking when necessary and the choice of the common neighbor w in $N'(u,v) \cap R'$ to be contracted with u or v is done in such a way that the minimum of $|(N'(x,y) \cap R') \setminus \{w\}|$ is maximized over all remaining missing edges $\{x,y\}$ in S.

The performance of these heuristics strongly depends on the instances. For PACE 2017 public instances, they work quite well. Table 3 shows the preprocessing result on the last 10 of those instances. See Section 8 for the description of those instances and the computational environment for the experiment. For each instance, the number of safe separators found and the maximum subproblem size in terms of the number of vertices, after the graph is decomposed by the safe separators found, are listed. The results show that these instances, which are deemed the hardest among all the 100 public instances, are quickly decomposed into manageable subproblems by our preprocessing.

Table 3 Safe separator preprocessing on PACE 2017 instances

On the other hand, these heuristics turned out useless for most of the DIMACS graph coloring instances: no safe separators are found for those instances. We suspect that this is not the limitation of the heuristics but is simply because those instances lack minor-safe separators. We need, however, further study to get a firm conclusion.

8 Performance results

We have tested our implementation on two sets of instances. The first set comes from the DIMACS graph coloring challenge [14] and has served as a standard benchmark suite for treewidth in the literature [13,5,15,19,4,2]. The other is the set of public instances posed by the exact treewidth track of PACE 2017 [16].

The computing environment for the experiment is as follows. CPU: Intel Core i7-7700K, 4.20GHz; RAM: 32GB; Operating system: Windows 10, 64bit; Programming language: Java 1.8; JVM: jre1.8.0_121. The maximum heap space size is 6GB by default and is 24GB where it is stated so. The implementation is single threaded, except that multiple threads may be invoked for garbage collection by JVM. The time measured is the CPU time, which includes the garbage collection time.

To determine the treewidth of a given instance we use our decision procedure with k being incremented one by one, starting from the obvious lower bound, namely the minimum degree of the graph. Binary search is not used because the cost of overshooting the exact treewidth can be huge. We do not feel the need of using stronger lower bounds either, since the cost of executing the decision procedure for k below such lower bounds is usually quite small.

Table 4 shows the results on DIMACS graph coloring instances. Each row shows the name of the instance, the number of vertices, the number of edges, the exact treewidth computed by our algorithm, CPU time in seconds, and the previously best known upper and lower bounds on the treewidth. Rows in bold face show the newly solved instances. For all but three of them, the previous best upper bound has turned out optimal: only the lower bound was weaker. In this experiment, however, no knowledge of previous bounds are used and our algorithm independently determines the exact treewidth.

The results on "queen" instances illustrate how far our algorithm has extended the practical limit of exact treewidth computation. Queen7_7 with 49 vertices is the largest instance previously solved, while queen10_10 with 100 vertices is now solved. Also note that all previously solved instances are fairly easy for our algorithm: all of them are solved within 10 seconds per instance and many of them within a second.

† 24GB heap space is used for these instances.

Table 4 Results on the DIMACS graph coloring instances

Table 5 shows the lower bounds obtained by our algorithm on unsolved DIMACS graph coloring instances. Lower bound entries in bold face are improvements over the previously known lower bounds. Computation time of the previously best lower bounds ranges from a few minutes to a week [6]. Detailed comparison of lower bound methods, which requires the normalization of machine speeds, is not intended here. Rather, the table is meant to show the potential of our algorithm as a lower bound procedure.

For many of the instances the improvements are significant. It can also be seen from this table that our algorithm performs rather poorly on relatively sparse graphs with a large number of vertices.

Table 5 New lower bounds on the treewidth of unsolved DIMACS graph coloring instances

Table 6 shows the results on PACE 2017 instances. The prefix "ex" in the instance names means that they are for the exact treewidth track. Odd numbers mean that they are public instances disclosed prior to the competition for testing and experimenting. Even numbered instances, not in the list, are secret and to be used in evaluating submissions. The time allowed to be spent for each instance is 30 minutes. As can be seen from the table, our algorithm solves all of the public instances with a large margin in time.

Table 6 Results on the PACE 2017 public instances

Acknowledgment

The author thanks Hiromu Ohtsuka for his help in implementing the block sieve data structure. He also thanks Yasuaki Kobayashi for helpful discussions and especially for drawing the author's attention to the notion of safe separators. This work would have been non-existent if not motivated by the timely challenges of PACE 2016 and 2017. The author is deeply indebted to their organizers, especially Holger Dell, for their dedication and excellent work.
