Abstract

Recent advances in blockchain technology suggest that the technology has potential in use in applications in a variety of new domains including spatio-temporal data management. The reliability and immutability of blockchains combined with the support for decentralized, trustless data processing offer new opportunities for applications in soch domains. However, current blockchain proposals do not support spatio-temporal data processing, and the block-based sequential access in blockchain hinders efficient query processing. We propose spatio-temporal blockchain technology that supports fast supports fast spatial queries by the introduction of a cryptographically signed tree data structure, the Merkle Block Space Index (BSI), which is a modification of the Merkle KD-tree. We consider Bitcoin line uniform block generation, and we process temporal queries by means of a block-DAG data structure, called Temporal Grap. Search (TGS), without the need for temporal indexes. To enable the experiments, we propose a random graph model to ger to a block-DAG topology for an abstract peer-to-peer network. We perform a comprehensive evaluation to offer insight into the applications, and effectiveness of the proposed technology. The evaluation indicates that TGS-BSI is a promising solution for ficien, spatio-temporal query processing on blockchains.

Keywords: Blockchains, spatio-temporal data, authenticated data structure, block-DAG

1. Introduction

Blockchain as a transformative technology has bound early use in the financial domain [1], but has recently found or plication in a variety of other domains. A bloc' chai i is a distributed, decentralized, and trustless ledger that a port the reliable and secure recording of transactions Blocks, in technology has demonstrated its applicability to be siness solutions in sectors such as finance, healthcare, and education [1, 2, 3]. Consider, for instance, a supply chair see ario where an object is tracked as it is undergoing trango ation. The tracking mechanism requires not only that t'e spatio emporal information is updated continuously, but nat queries regarding the object's time-varying location are also poperted. Typical queries include, for example, 'list all sojects at socation l at time t,' or 'list all objects that moved v ithin rao us r of location l during time interval $[t_1, t_2]$.' The support for such queries is desirable, for example, for logistic lecisions or product monitoring. However, a blockchain implementation of such a business scenario is challenging. For exam, 'a patio-temporal data grows at a higher rate than do. Consaction data currently supported by financial blockchan ystems. Further, consensus protocols

for spatio-temporal data require proof-of-location processing. Also, the sequential access mechanism in blockchains does not support efficient query processing.

The value proposition of blockchains over traditional databases is the data integrity through cryptographically signed historical data. For example, financial institutions require a signed 'append-only' data structure that is auditable and traceable [1, 4]. Large enterprise service providers such as Google or Amazon require spatio-temporal analytics on user data for providing continuous services in given time and space [5]. Therefore, a spatio-temporal blockchain system design should take into account two considerations, (i) the scale at which such a system is to be used, and (ii) the kind of query support that is required of the system.

It is not straightforward to directly adapt database concepts to a blockchain system. A spatio-temporal blockchain system design should consider secure data storage and efficient query processing simultaneously. This work provides a conceptual block design for efficient queries in block directed acyclic graphs (Block-DAG). Block-DAG is the blockchain alternative that makes possible to achieve high throughput by way of fast block creation.

More specifically, we consider spatio-temporal data processing in a blockchain setting and enable querying of blockchains without expensive local indexing. We integrate the Merkletree [6] with the spatial indexing such that spatio-temporal queries are supported without the need for additional indexes. Also,

we include additional timestamp information in block headers that enables temporal queries directly on blocks. We assume a spatio-temporal blockchain with an abstract consensus such that the credibility of the data is maintained by the consensus algorithm. We assume that a typical transaction has the following attributes: timestamp, longitude, latitude, and hashed account identifier. Overall, we enable blockchain for efficient query processing without the requirement of additional local indexes.

To summarize, data about moving objects can be stored in a spatio-temporal blockchain. Location services such as object tracking can enable many real-life tasks such as finding lost items [7], enabling autonomous delivery vehicles [8], and providing a foundation for next generation supply chains [9]. The advantages of distributed ledger technology are, however, often blocked by the technology's limitations in relation to real-life application domain requirements. One key such limitation is the lack of support for efficient queries directly on spatio-temporal blockchains. To the best of our knowledge, this work is the first attempt to enable efficient queries on spatio-temporal blockchains following the preliminary study [10].

We make the following specific contributions.

- 1. We propose the concept of block-DAG with pair-wise block order for spatio-temporal data storage that offers advantages over sequential blockchain access. We also propose improved block header organization that supporefficient spatio-temporal queries.
- 2. We introduce the Block Space Index (BSI) for block order to maintain the integrity of a block's body. We propose a variant of the Merkle Patricia tree to maintain the global current position change per account ar 1 also 1 to pose the TGS-BSI algorithm to enable span temporal queries on DAG-chains directly by traversing block aders.
- 3. We also propose simplified current position of fication on mobile clients that facilitates tracking of a product associated with a particular account. We use a Merkle-Patricia-trie on the peer side and local block header information on the client side to a the ize peer responses.
- 4. We propose a random-grapt model to generate a block-DAG topology for an abstract reer-to-peer network and demonstrate the effectiveness of the solution with the help of a detailed experimental study.

The rest of the paper is orga. 'zed as follows. Section 2 covers related concepts, and Section 3 provides an overview of the proposed approach. De ails about block construction and authenticated spatial index. If are resented in Section 4. Spatiotemporal query programs is covered in Section 5. A detailed empirical evaluation of resented in Section 6, and Section 7 concludes.

2. Preliminaries

Usecases of blockchain technology are motivated by business requirements. The initial considerations for crypto-currencies

were based on requirements such as decentralized authority, pseudo-anonymity, censorship-resistance, and reduced transaction fees. The resulting blockchair technology offers many benefits to users. These include, to 'spect the quality of products and services [11], to obtain efficient a. 'tamper-resistant digital content services [12], to real; c'amper-resistant real-time supply chains [13], to secure Ic f de ices [3, 14, 15], and to enable privacy preserving behavior a. (ytics [16].

The problem of indexing multi-Jimensional data is well studied in the database community, but lacks consideration in the context of blockchain systems. An existing study [17] offers a detailed coverage of spanio-temporal query processing. In this section, we brief y describe location encoding systems, spatio-temporal indexing, and a ithenticated spatial indexes. We also comment on the a transfer ges of block-DAG for spatio-temporal blockchain sata management.

2.1. Loc. ion End ding Systems

Location in formation is encoded in a variety of ways to enable location straing. In geographic coordinate systems, latitude and longitude are typically used to capture a point location. As include is an angular distance between -90° and 90° and represents a location South or North of Earth's equator. A longitude angular distance ranges between -180° and 180° and represents a location East or West of an imaginary line through Coenwich. An alternative representation is to use a space filling curve. The idea is to discretize space into cells, typically by means of a uniform grid. Then the cells are numbered by means of a curve that traverses all cells. A location is then represented by the number of the cell that it belongs to. A different approach, Geohash [18], encodes latitude-longitude pairs in a hierarchical data structure as unique strings.

2.2. Spatial Indexes

Spatial indexes typically store spatial locatons into a hierarchical data structure [19, 20, 21]. For example, the R-tree [22] and its variants, including the RT-tree [23] and the 3D R-tree [24] is a popular spatial index. The kd-tree performs better under the assumption of an initial bulk load and no subsequent data changes. This property makes it best suited for cases where the data is static. The kd-tree exhibits many favorable properties and has proven to be efficient in practice for low-dimensional data [25].

Another important aspect of data processing is data verification. Many authenticated data structures have been proposed for indexing spatial and spatio-temporal data to support verifiable queries such as range queries, *k*-NN queries, reverse *k*-NN queries, and skyline queries [26]. Authenticated versions of spatial indexes include the Merkle kd-tree [27] and the Merkle R-tree [28]. Proposals also exist for *k*-NN-based spatial queries [29].

2.3. NoSQL Multi-dimensional Indexing

Spatio-temporal indexing structures enable efficient query processing by maximizing the de-normalization capabilities [30].

Full-text search based database solutions are used widely to enable spatio-temporal analytics. Data storage is by way of specialized data structures similar to Bkd-trees [31]. GeoMesa [32] is an open-source distributed database system that supports spatio-temporal indexing using the *Z*-order curve to index space and time. Fox et al. [30] enable spatio-temporal indexing in NoSQL solutions where the data is de-normalized by way of column *families* and *qualifiers* that are implemented in the *Accumulo* NoSQL solution.

2.4. Blockchain Cryptography and Authenticated Index Basics

A collision-resistant hash function \mathcal{H} maps a string s to a bit vector of a fixed-length such that $\mathcal{H}(s)$ is fast to compute and it is computationally infeasible to find a collision as $\mathcal{H}(s_1) = \mathcal{H}(s_2)$ if $s_1 \neq s_2$ [33]. The Merkle Hash Tree (MHT) has proven to be a general base for a varity of authenticated DAG structures [34]. The MHT hierarchically organizes hashes to verify the integrity and validity of blocks by way of providing a tiny number of hashes or Verification Objects (VOs) [6]. These properties facilitate the applicability of MHT in blockchain systems [35] with use case specific adaptations. For example, Ethereum uses a Merkle Patricia trie to maintain the integrity of the global key-value states where the key is a 32-byte account identifier and the value is the account's state.

2.5. Blockchain for location

Location data has also been considered using the Blockchain technology. FOAM, as described by the authors [37], is a record col for decentralized geo-spatial data markets designed to enpower users to build a consensus-driven map of the world that can be trusted by applications. Another interesting xam_P is ChainSQL that integrates blockchain and database "chnoloty, thus enabling support for SQL in a blockchain setting 12" he study [15] proposes a spatio-temporal protocal to prove the locations in the setting of blockchain.

2.6. Blockchain and block-DAG

Bitcoin [1] and Ethereum [36] are v 11-known blockchain systems where transactions are public¹ / acc ssible in an anonymous way. The transaction accuracy is 1 even by the fact that consensus creates truth. Howeve, throughout in blockchain systems is a bottleneck as the tansa tion confirmation times are not comparable with those in data ase systems. Blockchain performance is strongly cour ed with the lying consensus protocol and hard-coded limita ons on computations per block. The concept of block-DAG [4, in 1 sed on the idea of multiple references from every block to its predecessor blocks with possible conflicting tran actions. As a consequence, this leads to changed transaction acceptage rules, where the graph topology is used directly 's v...' that help identify a robust subset of a block-DAG w. ', no conflicting transactions. A block references all the blocks hat its miner was aware at the time of block creation. Thus, the blocks that take a long time to propagate are prone to be rejected by the system. A block is considered valid only if all of its predecessors are valid and are known by the node. Thus, if a block B_i references some block

Table 1: Frequently used notation

Symbol	Meaning
В	Block; B_{header} : block neader; B_{size} : block size
D	Dataset $D = \{x x \in \mathbb{R}^a\}, $ ' dimensionality
${\mathcal D}$	Network delay
G(V,E)	Topology of a block DAG; V: set of blocks;
	E: set of reference
$\mathcal H$	Crypto graphic Hash Linction
\mathcal{H}_R	Merkle ha oot tu. ction
${\mathcal T}$	Transact on; 'r. Transaction rate per second;
	\mathcal{T}_n : Total \mathcal{T} asactions
$g_{\mathcal{T}}$	Cryp $\mathcal{I}_{\mathcal{S}}$ raphically signed \mathcal{T} by user's PRIVKEY
k	Ans wer points in k-NN and bounded k-NN
q	Hype \cdot -recta gle space range $q = [x, y]$ or
	point $a = \{x\}$ where $x, y \in D$
r	Re .ius; b: bounding radius
α	Stand ² d deviation s.t. $\mathcal{N}(\mathcal{T}_r, \alpha^2)$
β	The range s.t. [β .start_time, β .end_time]
σ	De erministic search procedure
n [36]	$_{\beta}$: Time range search on $G(V, E)$ by β
	σ_q : Range search; σ_{q,r_b} : Ball-point search
	$\sigma_{k,q}$: k-NN search; σ_{k,q,r_b} : Bounded k-NN
$(\phi, \Lambda,$	(Latitude, Longitude)

 B_j , there is no need to reference the predecessors of B_j ; this is implied. To ensure the stable working of block-DAG based systems, miners (i) must reference the valid points of the DAG, and (ii) should quickly broadcast blocks they create or receive. In a block-DAG, there is no assumption that all miners share the exact same view of the DAG at all times.

3. Problem Formulation

In this section, we present related concepts, definitions, and assumptions. We rely on the block-DAG paradigm as an alternative to blockchain and propose a block header that aims to allow efficient spatio-temporal query processing. Table 1 provides an overview of frequently used notation.

3.1. Related Concepts

We first formalize concepts including transaction, block, and block header.

Transaction. A transaction, formally \mathcal{T} , is a set of attributes including longitude, latitude, timestamp (t), and hashed account identifier (uid) or the public-key of the transaction creator. We assume that the system records only spatio-temporal information. A transaction is a single instruction that is verified through a cryptographic-signature of the transaction hash $g_{\mathcal{T}} = Enc(\mathcal{H}(\mathcal{T}))$ while the block formation is on peer side. To include \mathcal{T} to B_{body} a peer receives from a user the transaction data, the digital signature of the transaction $g_{\mathcal{T}}$, and the user's public key PUBKEY.

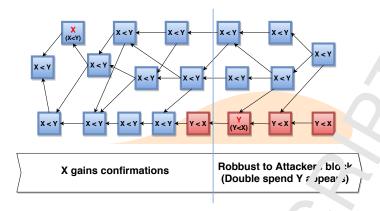

Figure 1: In a block-DAG, each block references all blocks to which its miner was aware at the time of s creation. The blocks, that take a long time to propagate (conflicting transactions) are ignored (red color).

Block. A block, formally $B = (B_{header}, B_{body})$, includes a block header B_{header} and an associated list of transactions B_{body} ordered w.r.t. the leaves in Merkle kd-tree that is organized by a bulk load algorithm which is applied to B_{body} .

Block header. A block header, formally B_{header} , contains information related to transactions and a set of hashes of other block headers. The block header maintains a spatial index per block. For the spatial indexes per block, following properties should hold: (i) header must be authenticated to guarantee the every other ledger holder has the similarly built index structure, (ii) spatial query support similar to range query, nearest naighbor query, ball query, etc., and (iii) fast access and verifiction from the last position of a particular item that is associated with its hashed account identifier. To avoid addition at a dexing of the whole block-DAG, we use Merkle kd-tree for its ifunctionality, i.e., block integrity verification similar a Ritc in and fast spatial queries on a block. For simplified cu rent position verification, we use Merkle-Patricia-trie and l cation root hash value from a particular block header. The b. a' header contains the following information:

blockID: a unique identifier $\mathcal{H}(B_{hea} \otimes r)$.

orphanHashes: a list of hashes of rearenced block headers.

locationRoot: a 256-bit hash c, the loot node of the Merkle patricia trie populated with all the ccol at identifiers and associated with the most recent location, time and number of records per account.

merkleSpaceRoot: a 25-bit mush of the root node of the Merkle kd-tree popul ted with each transaction of the block.

startTime: a scalar value \mathcal{T} all to $\forall \mathcal{T} \in B_{body} : min(\mathcal{T}.t)$.

endTime: a scalar $\exists f$ e equal to $\forall \mathcal{T} \in B_{body} : max(\mathcal{T}.t)$.

timestamp: is the time of block creation.

nonce: a 64-bit hash which proves that sufficient amount of computation has been carried during block creation.

3.2. Definitions

We form 'lly denote block-DAG as G. G enforces a causal relation among blocks which states that if block B_i includes the bash of block B_j , then B_i must have been created after B_j . Although block-DAG supports fast block creation and short the speed of transaction to be securely confirmed in a support of the speed of transaction to be securely confirmed in a support of the speed of transaction to be securely confirmed in a support of the speed of transaction to be securely confirmed in a support of the speed of transaction to be securely confirmed in a support of the speed of transaction to be securely confirmed in a support of the speed of transaction of the speed of transaction of the speed of transactions.

Definition 1 (input). A subset of confirmed transactions in G are the input of T and belong to the owner of T.

Definition 2 (conflict). *Transactions* \mathcal{T}_1 *and* \mathcal{T}_2 *are conflicting transactions iff* $\mathcal{T}_1.uid = \mathcal{T}_2.uid$ *and* $\mathcal{T}_1.t = \mathcal{T}_2.t$.

Property 1 (Adjusted Consistency). \mathcal{T}_1 is accepted iff $\forall \mathcal{T}_i \in input(\mathcal{T}) : \mathcal{T}_i \in GetRobustAccepted(G)$, all conflicts are rejected and the time-stamp of transaction \mathcal{T} is not more than δ -away from current time-stamp. δ is system defined.

The Adjusted Consistency property ensures a real system clock as the time-stamp in user transactions is user-defined and the system accepts transactions satisfied by δ only.

Property 2 (Weak Liveness). *If transaction* \mathcal{T}_i *is published in G and no conflicting* \mathcal{T}_j *is published, then it is included in GetRobustAccepted*(G).

Property 3 (Pairwise ordering). Once block B is published in G, the system guarantees that G contains blocks published before or exactly after B.

Property 4 (Result Completeness). A response set for a user query must not have any missing results.

Property 5 (Block Soundness). No modification takes place in the B_{body} , neither by adding non-existence transactions nor by modifying existing ones.

A miner is expected to maintain the SPECTRE voting protocol to reveal the real order between each pair of blocks on

the local image of *G*. The protocol holds these properties and states for fast block creation (at least five blocks per second). The aforementioned properties and a fast block creation rate allow the temporal queries to proceed over block-DAG topology without additional temporal indexes. Note that we also consider the case of a Light Node such as a mobile client which does not store the entire block-DAG [1].

Remark. The spatio-temporal block-DAG does not require a linear order among all the transactions because the tracking actions of an account don't affect other account actions. The linear ordering limits throughput in a blockchain and results in low block creation rate. This is a concern as the spatio-temporal data grows massively as a tracking object reports spatio-temporal information on a regular basis. Block-DAG is an alternative that makes possible to handle high throughput by implementing a fast block creation scheme. For the rest of this work, we use the terms blockchain and block-DAG, interchangeably. In this work, we assume that the transactions associated with an object have a linear order.

4. Enabling Block-DAG for Spatio-Temporal Queries

A transaction typically includes geodesic coordinates, *latitude* ϕ and *longitude* λ , to represent a location.

4.1. Geo-spatial Representation and Spatial Index

For queries such as k-NN, range, and ball-point querie we need a Cartesian coordinate system represented by orthogon. I axis. For the purpose, 'map projection' is used to convert the geodesic system to two-dimensional coordinates or the map. Nonetheless, it does not matter which coordinate system or a cographic standard is used, as it is not possible to make a projection from a sphere onto a rectangle, i.e., a two-2 is system, and save all data, i.e., angles and distances, simultation of sly.

Example. Haversine is a measure to get e_{j_1} example. To use it on Earth with an approximate radius $r_e = 6371km$, consider three reference points $A = \{50^\circ, 50^\circ\}$, $B = \{50^\circ, 51^\circ\}$, and $C = \{51^\circ, 50^\circ\}$. For points A, B, and C, 2D coordinate system tells that they are equidistant based on Euclidean distance. But given late udir all difference $\delta \phi = \phi_2 - \phi_1$, and the longitudinal difference $\delta \phi = \lambda_2 - \lambda_1$ for pairs (A, B) and (A, C) according to Haver the (E_{k_1}, I) , the distance from point A to B is 111.19 km, but the distance from A to C is 71.47 km. That is why taking latit the and ongitude values directly to a kd-tree is incorrect e_{j_1} , fails to compute k-NN and range queries by using euclidean distance. We compute Haversine distance as follows:

$$dist_{harv} = 2 r_e \arcsin(i \cdot i r_1) \sqrt{\sin^2(\frac{\delta \phi}{2}) + \cos\phi_i \cos\phi_j \sin^2(\frac{\delta \lambda}{2})}]$$
(1)

For the *k*-NN and bounded *k*-NN search problems, a magnitude-comparable distance can be substituted for the relative distance since the relative ordering of the distances is more important than the actual distances [38]. The tunnel-through distance for

points i and j is Eq. 3. For each index, we pre-compute Cartesian coordinates given by the latitude and longitude using Eq. 2 and store these on a Merkle kd-tre γ .

$$x_{i} = r_{e}cos(c_{i}) \cdot s(\phi_{i})$$

$$y_{i} = r_{e}sir(c_{i})cos(\phi_{i})$$

$$z_{i} = r_{e}in(\phi_{i})$$
(2)

$$dist = \sqrt{(x_i - x_j) \cdot (y_i - y_j)^2 - (z_i - z_j)^2)}$$
 (3)

4.2. Spatial Index p r Bl ck

The Merkle Hash 1. a. or MHT, is generally used as a base for arbitra y authoricated directed acyclic graph structures. The schene to do verification proposed on MHT is as follows: recompute in ash value incrementally by recreating Merkle treoroot on a particular block as shown in Eq. 4.

$$\mathcal{H}_{R}(\cdots) = \begin{cases} r_{i} \text{ byte}(v_{i}), & v_{i} \text{: leaf node} \\ \mathcal{H}(v_{i}, \mathcal{H}_{R}(v_{i,1}), ..., \mathcal{H}_{R}(v_{i,n})), & v_{i,j} \text{: successors of } v_{i} \end{cases}$$
(4)

As More let ree is designed for spatial queries only, we require a data structure that is able to process spatio-temporal queries. The SPECTRE protocol states that the block creation is ypically within one second and the size of a block is expected to be within 40-70 transactions. We consider a three-limensional space, i.e., a sphere in a Cartesian space along with an additional set of points, and use kd-tree for the purpose. A kd-tree has the advantage that it fits in the main memory and avoids a complicated structure similar to 3D R-tree with additional minimum bounding box coordinates. The kd-tree at each level has the Euclidean distance in one dimension and therefore has a reasonable performance for processing k-NN, range, and ball-point queries.

In this work, we consider a kd-tree authenticated by the Merkle scheme, i.e., an Mkd-tree, and propose a modification of Mkd-tree which we call Block Space Index or BSI. BSI stores one hash value for every node which is computed from the left and right hashes using Eq. 4. Location points are stored in the internal nodes of BSI. The leaves of BSI store transaction hash values where each leaf-hash is associated with the hash of internal node using Depth First Search as shown in Figure 3.

The bulk loading of BSI from the prepared list of transactions \mathcal{T}_{list} for a block formation is presented in algorithm 1 where t is a timestamp of $\mathcal{T} \in \mathcal{T}_{list}$. The resultant reordered list of transactions \mathcal{M} is written to the block and BSI is formed from \mathcal{M} .

Lightweight Client. We also consider the case of a Light Node, for instance, a mobile device, which does not store the entire block-DAG. A light client only needs to query node headers from the peer-to-peer network and select locally the valid parts by topological voting procedure over the network that is handled by SPECTRE protocol. A typical proof of transaction inclusion is handled by BSI. For the same, we send a verification object, VO, with the results of spatio-temporal queries to a lightweight client.

Algorithm 1 An outline of the steps for BulkLoad routine

Require: \mathcal{T}_{list} , μ , $\mathcal{M} \leftarrow \emptyset$ $\Rightarrow \mu$: recursion depth; \mathcal{M} : empty

Ensure: $\mathcal{T}_{list} \leftarrow \{\mathcal{T}.(X,Y,Z) \leftarrow \mathcal{T}.(\phi,\lambda) \forall \mathcal{T} \in \mathcal{T}_{list}\}; \quad \triangleright \mathcal{T}_{list} \text{ to Cartesian space}$

- 2: $\mathcal{T}_{list} \leftarrow sorted(\mathcal{T}_{list}, by \mathcal{T}.(X, Y, Z)[\sigma] \ and \mathcal{T}.t) \Rightarrow Sort rest of transactions$
- 3: \mathcal{T}_{left} , m, $\mathcal{T}_{right} \leftarrow \text{medianSplit}(\mathcal{T}_{list}) \rightarrow m$: root of splitting
- 4: $\mathcal{M} \leftarrow m$;
- 5: BulkLoad(\mathcal{T}_{left} , $\mu + 1$, \mathcal{M}) > Recursion build left subtree
- 6: BulkLoad(\mathcal{T}_{right} , $\mu + 1$, \mathcal{M}) > Recursion build right subtree
- 7: return M

4.3. Simplified Last Position Verification

In this section, we discuss account management and account location tracking.

4.3.1. Account Management

An *account* is a personal data that is associated with a hashed public key of a user's initially generated *key-pair*. The account includes the last record of space-time location and the number of stored transactions per account. The state of all accounts is the state of the whole block-DAG network. In then system, accounts are needed for tracking entities associated with the accounts. The presented block-DAG platform is a public transaction-based state machine that initiates from the g_{ℓ} block, or *genesis state*, and incrementally updates the location position of associated anonymous accounts up to the last location or final state.

The main challenge of account management in chlockchain is frequent updates of values for each account. There are an authenticated data-structure that holds all the a court information is different from managing transaction have y in oinary trees. We utilize Merkle Patricia-trie (MPT) and reflects associations between each account identifier and the account information includes geodesic coordinates of the most recent geodesic coordinates geodesic coordinates of the most recent geodesic coordinates geodesic coordinates geodesic coordinates geodesic coordinates geodesic coordinates geodesic coordinate

To efficiently support account state, MPT has the following features: (i) it is an authenticated a structure and is able to quickly recalculate a tree roc after an insert or update operation such as create or updat account or update the last geolocation and timestamp, (ii) tree roch is dependent on data and not the order in which updates are made, (iii) fast roll-back is supported to construct global block state that only has the fresh account information and in torm in the block, and (iv) it enables answering account the countries, for example, 'what is the most recent position of account x?' or 'does account with id xxx-xx exists?'.

The value of MPT root or location root in the block header reflects a distinct version of the global state per block. The MPT implementation introduces a value driven data-structure through referencing each node by its hash, therefore, key-value is stored in a levelDB database where the value is the string representation of a node and the key is its hash. Thus, multiple copies of the historical states of each node allow fast roll-back. MPT consist of three types of notes: (i) a leaf node that stores key-value pairs, (ii) an extension node that stores a hash of another node, and (iii) fixed length sets of branch nodes typically having 17 elements. The first 15 elements correspond to the sixteen possible hex charactethin a key, and the final element holds a value if there is a key-value pair where the key ends at the branch node. A same part of MPT version for a block is shown in Figure 2.

Note that in a bloch hain, the state of MPT changes just from one block of another, but the block-DAG allows several references from a block of other blocks that adds to the complexity of the contraction of MPT. In Algorithm 2, we introduce steps for a spenshot of MPT formation per block.

Algorith. 2 Ar a cline of steps for CreateSnapshotMPT

Theorem 1. For each block from GetRobustAccepted(G), the last position of an account queried from MPT has the completeness of query answer (property 4).

Proof. Property 1 guarantees absence of conflicting transactions. The properties of MPT ((ii)-(iii) above) ensure a unique tree root value. Property 3 guarantees a monotonically decreasing time from a block to referenced blocks.

4.3.2. Account Location Tracking

We use MPT and a *location root* from a block header for most recent position of an object. We assume that the block headers are already available. A lightweight client tracks items by hashed account identifier (*uid*) that is a hashed from the public part of a key pair. For most recent location verification of an object, we consider the following steps:

- (1) A lightweight client has a fresh state of the block-DAG.
- (2) The client requests from the peers to get an *account state* by the predefined *uid* that stores the most recent position and a time-stamp.
- (3) The request is handled on peer side by MPT authenticated data structure. Request result includes the account state and additional information for authorization. The

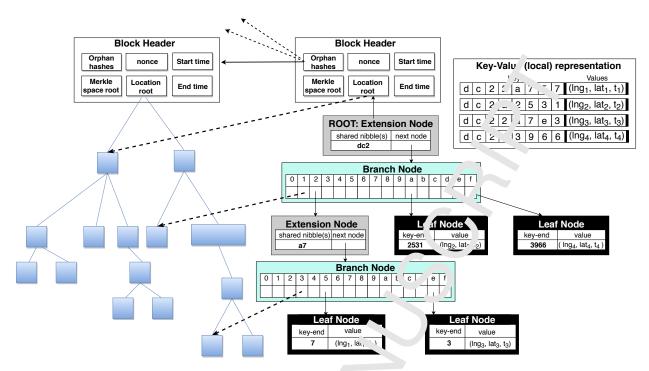

Figure 2: The last positions of objects related to accounts are represented by key-value pairs and encoded in Merkle Patricia-trie.

authorization information consists of an array of verification objects, VOs, reported by MPT in time-order and the block identifier of a B_{header} that includes *location root* hash-value corresponding to a fresh version of the array of the peer side.

- (4) The client computes the 'Location root' of ar object by hashing \mathcal{H} (obtained account state) with the 'Os.
- (5) The client locally verifies the result on lo al block-DAG image with the help of block identifier and Location root from the previous step. If the verifier ion is guidessful, we have the verified most recent location along with a time-stamp for the client.

5. Spatio-temporal Queries on block 7 G

In this section, we present the queries for the data structures described in section 4. We first course emporal queries on block-DAG.

5.1. Temporal Queries on blo 1-DAC

To enable a fast temporal search over the block-DAG, we introduce a temporal meta-information included in each block header. The temporal range α ery with a given time range β over block-DAG is the aniministic search procedure P over block-DAG topology C^C , E) that we name as T emporal G and G has multiple source nodes G, which are recent nodes with a reference to the previous points, for each G and G temporal range search (G is implemented in a breadth-first (BFS) manner, the steps of which are listed below:

- (1) Given a time range $\beta = (start_time, end_time)$, start BFS from the tips of the GetRobustAccepted(G).
- (2) When reach a block-header B_{header} such that $[B_{header}.start_time, B_{header}.end_time] \cap [\beta.start_time, \beta.end_time] \neq \emptyset$, the B_{header} is included in the result set.
- (3) The BFS runs until no new B_{header} occurs in range β and all the next B_{header} .end_time < β .start_time.

Theorem 2. Temporal Graph Search procedure has the completeness of query answer (property 4) over $GetRobustAccepted(G) \subset G$ of block-DAG topology (G).

Proof. Property 3 guarantees monotonically decreasing timestamps of $B_{header}.start_time$ and $B_{header}.end_time$ for each step of TGS procedure. The σ_{β} accepts blocks as partial intersection of time ranges. Therefore, the algorithm has the property 4, nonetheless, a tiny number of outline transactions will be in result set that leads to an unsound answer.

5.2. Spatial Queries per Block

The spatio-temporal query is the combination of the two consequent procedure calls. The first part is the TGS procedure that results in a set of block headers \mathcal{M}_{β} . The second part is the spatial query over BSI of each block header. A general spatial search result is denoted as $\sigma(\mathcal{M}_{\beta}) = \{\sigma(BSI(B_{header}))\}$ $\forall B_{header} \in \mathcal{M}_{\beta}$. We now present the standalone mechanism of spatial queries.

The BSI is the extension of Merkle kd-tree, where each internal node of the data structure is the final space point. In this work, we use a three dimensional BSI for the three distinct coordinates in the Cartesian coordinate system. With BSI, we are

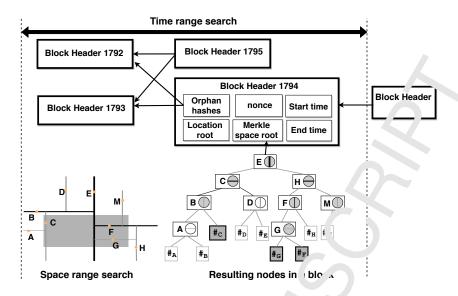

Figure 3: Spatio-temporal range search on block-DAG by TGS-BSI procedure: first, filter by ten, and procedure σ_{β} , and given time range β , apply space range query on each BSI by a given hyper-rectangle $\alpha = \{x, y\}$.

able to handle efficient space query per block for the following types of queries: (i) *range query*, (ii) *k-NN query*, (iii) *bounded k-NN query*, and (iv) *ball-point query*, the details of which are presented below.

5.2.1. Range query

Range query, σ_q , is stated as follows: Given a dataset of points D, and a range $q = \{x\}$ where $x \in \mathbb{R}^d$, range query so its each $s \in D$ that is located inside the hyper-rectangle constituted by q. The computational cost of a range query for the result points of $O(\sqrt{B_{size}} + k)$ where k is the number of result points.

Given a query hyper-rectangle q, the range earch for each $B_{header} \in \mathcal{M}_{\beta}$ starts at the root and recursively averses the tree pruning a subtree if its root does not intersect with. A rexample of a spatio-temporal range query on bink-DAG is shown in Figure 3. We show a 2D BSI for ease of illustration.

5.2.2. K-nearest neighbors

k-NN query, $\sigma_{k,q}$, is defined as follow. Given a dataset of points D, a scalar value k, and a query point $q = \{x\}$ where $x \in \mathcal{R}^d$, $\sigma_{k,q}(D)$ returns a subscoof a points from D that are closest to q. The average computation 1 omplexity of a k-NN query for a block is $O(3B_{si}/k)$ assuming that the number of dimensions of BSI is fixed (3.2).

The k-NN algorithm r inta.... a priority queue to keep k closest points. The firs k point are en-queued and the algorithm traverses down the tree sk pping bounding boxes where is no chance to get a point closer than the points in k. Thus, the performance of the algorithm depends on quickly reaching nearby points. The fine stage is to aggregate the top-k points from $\sigma_{k,q}(\mathcal{M}_{\beta})$.

5.2.3. Bounded k-nearest neighbors

Bounded k-NN, σ_{q,r_b} , is defined as follows: Given a dataset of points D, a scalar value k, a scalar value of the bounding

radius r_b . $\neg d$ a query point $q = \{x\}$ where $x \in \mathbb{R}^d$, $\sigma_{k,q,r_b}(D)$, a $k \in \mathbb{N}^d$ query returns a subset of points in D of size $\leq k$ that are closes. \neg the q inside a hyper-sphere of radius r_b centered at q. In α rage case complexity of a bounded k-NN query is also $(3B_{size}k)$ considering that the number of dimensions in BSI is fix. d at 3D.

The query algorithm includes additional boundary to a maxmum radius that creates a limiting hyper-sphere for exploration during the BSI tree traversal. Bounded k-NN maintains k current best points and search branches in BSI when they can't have points closer than any of the k current points, or if the radius is more than a boundary radius r_b . The final stage is to aggregate the top-k points from $\sigma_{k,q}(\mathcal{M}_{\beta})$.

5.2.4. Ball-Point Query

Given a dataset of points D, radius r_b , and a point $q = \{x\}$ where $x \in \mathcal{R}^d$, a ball-point query, σ_{k,q,r_b} , seeks each $s \in D$ that is in a sphere of radius r_b centered at the point q. The average case computational complexity of a ball-point query average for a particular block is $O(3\sqrt{B_{size}} + k)$ where k is the number of answer points.

Given a bounding radius r_b , and a centering point q the ballpoint query for each $B_{header} \in \mathcal{M}_{\beta}$ starts at the root and recursively traverses the tree whilst pruning a bounding box that does not intersect the hypersphere of radius = r_b centered at q.

6. Experimental Evaluation

We now present a detailed evaluation of spatio-temporal queries over blockchain. We first present the random graph model for block-DAG generation. Then, we describe the experimental setup that is followed by the evaluation results and discussion.

Algorithm 3 An outline of the steps for GenBlockDAG routine

```
Require: \mathcal{T}_n, \mathcal{T}_r, \alpha, \mathcal{D}, B_{size}
  1: \mathcal{T}_{rlist} \leftarrow \text{gen}(\mathcal{N}(\mathcal{T}_r, \alpha^2), \mathcal{T}_n)
                                                           ▶ list of various transaction
      rates per second
 2: (V, E) \leftarrow (\text{genesis block}, \emptyset) \rightarrow \text{initialize vertices and block}
      references
                       > remainder of transactions from previous chunk
 3: \omega \leftarrow 0
  4: for each chunk c of size \mathcal{D} from \mathcal{T}_{rlist} do
               \mathcal{B} \leftarrow \text{round}((\text{sum}(c) + \omega)/B_{size})
 5:
                                                                                     ▶ number of
      unconnected blocks while \mathcal{D}
               E \leftarrow \text{(connect all } \mathcal{B} \text{ to orphans of } V\text{)}
  6:
               V \leftarrow \mathcal{B}
  7:
               \omega \leftarrow (\operatorname{sum}(c) + \omega) \mod B_{size}
  8:
  9: return (V, E)
```

6.1. Random Graph Model for block-DAG

The synthetic topology structure of block-DAG is generated by Algorithm 3. The following parameters are considered for block-DAG generation: network delay \mathcal{D} , number of transactions per second \mathcal{T}_r , total number of transactions \mathcal{T}_n , block size B_{size} , and a standard deviation α for a normal distribution centered at \mathcal{T}_r . The generation model is based on the following assumptions: (i) two honest blocks created at the same time are not mutually reachable, and (ii) no more than n honest unconnected blocks can be created at the same time when $n = \mathcal{D} * B_{rate}$ and B_{rate} is block creation rate.

6.2. *Setup*

For the experiments, we consider a spatio-temmporal dataset, 'Pokeman Go'. The dataset includes 18732 records where each record contains latitude, longitude, timestamp and a Pokeman type. We assume a constant and intensive transaction flot. In order to simulate a computing extensive environment, we replicate the dataset 300 times. Thereafter, we generate holock-DAG with the assumption that the network delay is typically 3 seconds, $\mathcal{T}_r = 60$, $B_{size} = 50$, $\alpha^2 = 3$, and \mathcal{T}_n is 300 times the Pokemon Go dataset size. As the record are duplicated, the timestamps are updated in accordance with the original dataset.

For query performance measuremen, we repeat each experiment ten times at each testing oint to get a descriptive and robust median point. The implementation are in Python and the results are obtained on a Linux man bine with Intel Core i7-6700 CPU 3.40GHz process or, and 16 GB RAM. The query times reported in the following text are in 000's milliseconds, e.g. we say '3 units' wher the nature 3000 milliseconds.

6.3. Spatio-temporal Quarry Performance Analysis

We evaluate the reformance of spatio-temporal queries (Section 5): (i) for tempo, 1r ange upto 2 weeks, (ii) for increasing number of hours over a block-DAG with $B_{size} = 40$, and (iii) $B_{size} = 100$, (iv) performance change for a fixed temporal range, 2 hours, for increasing number of transactions included in the block-DAG. In another set of experiments, we evaluate query performance of spatial queries: (i) for varying values of k for

k-NN query, (ii) varying bounding radius r_b for bounded k-NN query, and (iii) ball-point query.

In another set of experiments we evaluate the queries under study for spatio-temporal dath handling. As the scan operation for a blockchain is a brute lorce wration over every block, a temporal search must go the ghall the entries of a blockheader due to the absence of the estamp information within. For performance comparison, we consider the following: (a) scan operation that firstly were transactions by time and then by space, SCAN time- pare, and vice versa, SCAN space-time, and (b) our proposer time graph search, TGS, and blockchain space index, BSI, for specio-temporal querying, TGS-BSI.

6.3.1. Block siz

Block size B_{siz} is the number of transactions in a block and this information: stored in the block header. We report median query in a in this (000's milliseconds) as we increase B_{size} from 30 to 11. The observations of Figure 4 state that an increase in block-size improves query performance for TGS-BSI as more printing occurs in each block that reduces the total number of observations to be considered. As the synthetic block-DAS is for a two week period, the spatio-temporal query to, two weeks temporal range leads to a spatial query.

We beerve in Figure 4 that the query time decreases when the orack size B_{size} increases. The running times for k-NN and ι unded k-NN queries are shown in Figure 4 (ii)–(iii). For $B_{size}=30$, the TGS-BSI query time is 7.5 units and it decreases to 1 unit for $B_{size}=100$, while the k-NN scan queries require 17.5 units. The overall query performance remains stable for range and ball queries, e.g. for TGS-BSI queries, running time remains below 2 units whereas for scan queries the running time is 5 units and upwards.

It can be observed that the block size is an important parameter for k-NN query performance and as the block size increases, pruning is more effective for TGS-BSI. Nonetheless, in real applications, we expect that the average B_{size} will typically remain below 100.

6.3.2. Temporal range

We now report time range β results for spatio-temporal queries. Scan operation handles temporal queries by scanning timestamps for each transaction whereas TGS-BSI is a breadth-first search over the block-DAG that stores timestamp attribute on each node. We also consider more realistic short temporal ranges from 0.5 hours to 12 hours. The performance evaluations are shown for two cases: (i) $B_{size} = 40$, Figure 5, and (ii) $B_{size} = 100$, Figure 6.

For the experiments, we increase β from 0.5 hours to 12 hours and observe that the running time increases linearly with β , however, time-space scan operation is noticeably time consuming. The results of TGS-BSI for k-NN and bounded k-NN queries for two variants of experiments presented in Figure 5 (ii)–(iii), and Figure 6 (ii)–(iii), show that for $B_{size}=100$ the running time is almost half compared to the running time for $B_{size}=40$. However, the overall time for TGS-BSI remains stable for range and ball-point queries.

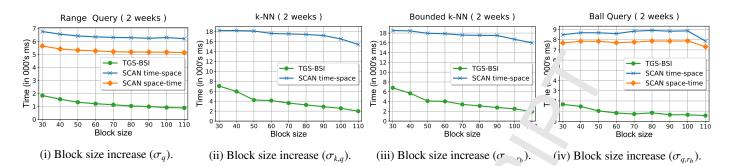

Figure 4: Performance evaluation for increasing B_{size} from 30 to 110 over a 2 we k synulation block-DAG. Query parameters: $\beta = 2$ weeks, $q = (\phi, \lambda) = (22.6, 114)$, k = 15, $r_b = 5$.

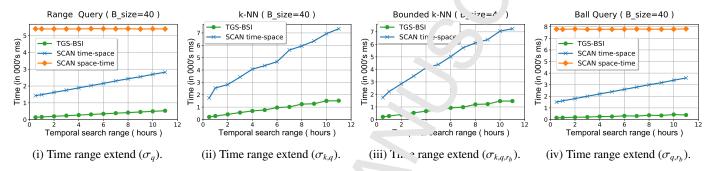

Figure 5: Performance evaluation for increasing time range β from 0.5 h. vr to 12 hours over a 2 week synthetic block-DAG with $B_{size} = 40$. Query parameters: $q = (e^{(-1)}) = (2, 6, 114), k = 15, r_b = 15$.

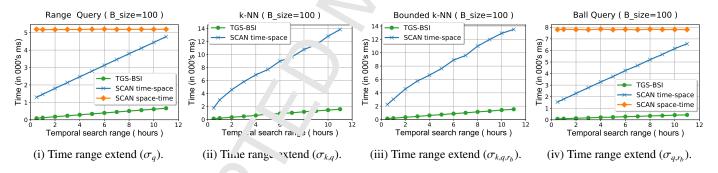

Figure 6: Performance evaluation for acrea and time range β from 0.5 hours to 12 hours over a 2 week synthetic block-DAG with $B_{size} = 100$. Calcary parameters: $q = (\phi, \lambda) = (22.6, 114), k = 15, r_b = 15$.

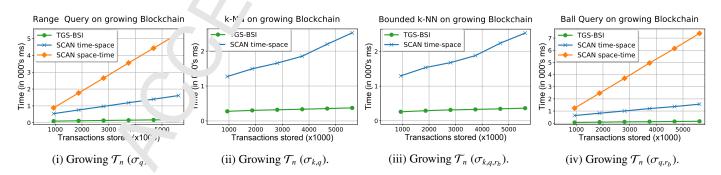

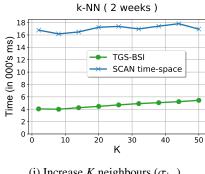

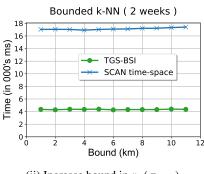

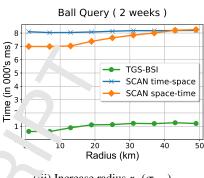

Figure 7: Performance evaluation for increasing \mathcal{T}_n from 10^6 to $6*10^6$ transactions over a 2 week synthetic block-DAG. Query parameters: $\beta=2$ weeks, $q=(\phi,\lambda)=(22.6,114), k=15, r_b=15$.

(i) Increase K neighbours $(\sigma_{k,q})$.

(ii) Increase bound in r_b (σ_{k,q,r_b}).

(iii) Increase radius r_b (σ_{q,r_b}).

Figure 8: Performance evaluation over a 2 week synthetic block-DAG. We vary number of neighbors k fr ... 1 to 50 to. k-NN search, bounding radius r_b from 1 to 11 km for bounded k-NN search and bounding radius from 1 to 50 for ball-point query. Query paramet s: $\beta = 2$ w eks, $q = (\phi, \lambda) = (22.6, 114), k = 15, r_b = 15$.

6.3.3. Number of transactions stored

We also test the scalability of the algorithms we study for increasing number of transactions \mathcal{T}_n stored in a block-DAG. We report the running times as we increase \mathcal{T}_n from 10^6 to $6*10^6$ in a synthetic block-DAG. The size of block-DAG and the running time results are shown in Figure 7 (i)-(iv). It can be observed that TGS-BSI performs significantly better than scan-range operations. As growing number of transactions are accepted in a decentralized ledger, it becomes clear that TGS-BSI query performance is encouraging as it outperforms scan-range search by orders of magnitude.

6.3.4. Query parameters

In addition to the above experiments, we study query per formance in a 2 week temporal range, Figure 8, for the following three parameters: number of nearest neighbors κ for k-NN queries, Figure 8(i), bounding radius r_h for rounded k-NN, Figure 8(ii), and increasing bounding radius for bail mint query, Figure 8(iii).

We report running times as we increase k from 1 up t 50 for the k-NN query in Figure 8(i). It can be observed that the query time increases linearly with the increasing v_a as of k. TGS-BSI outperforms scan-range for k-NN every. Similar trends can be observed for increasing r_b for b and $\pm k$ -NN query, Figure 8(ii). We also observe that the over 1 time for TGS-BSI remains stable even for harder instances.

In summary, block-DAG ba ed 7 GS-DSI is a promising approach that provides significant spendy of or spatio-temporal queries on blockchain. As a hock-DAG is a significantly compact data structure and TGS-1 SI is cus omized to answer queries under study, we conjecture that the performance of TGS-BSI is bound to improve for more realistic large datasets. Further, block-DAG is customiz, ble for specific applications and TGS-BSI can be enhanced to we have additional query types.

7. Conclusion and Fuvre Work

We have presented efficient spatio-temporal data storage and query processing in public decentralized ledgers that maintain integrity through cryptographically signed history in block-DAG and enable efficient spatio-temporal queries without additional

local index ng. Vie Iso presented a protocol for authenticated tracking of a set of entities based on the public key or hashed account ioc rifier. We considered four types of queries in this work and reported on performance evaluation of range query, k-NN query, h unded k-NN query, and ball-point query. The experi. Intal results demonstrated the effectiveness and applicalling in the solution for real-life applications.

this is one of the initial studies on the topic, a number foren directions remain. For example, a study on client-peer are amunication seems an interesting idea as it is crucial to enat 'e lightweight clients at the edge of the network to access the at a from block-DAG peers in an effective way. Further, due to the presence of malicious peers, query authentication should also be an important consideration. Additionally, the extension of spatio-temporal queries to more sophisticated queries, for instance, 'find all pairs of points whose distance is at most k within a time bounds', skyline k-NN query, reverse k-NN, etc., is also an interesting direction to explore. Another interesting idea is to extend query computation to decentralized Map-Reduce framework and support OLAP like queries [39, 40] on a large number of blocks.

QIANG QU is an associate professor at Shenzhen Institutes of Advanced Technology, Chinese Academy of Sciences (CAS), and the director of Guangdong Provincial R&D Center of Blockchain and Distributed IoT Security. He is a candidate of the CAS Poincer Hundred Talents Program. He received the MSc degree in Computer science from Peking University and the PhD degree from Aarhus University. His current research interests are in data-intensive applications and systems, focusing on efficient and scalable

algorithm design, blockchain, data sense-making, and mobility intelligence. His recent research has been published in leading journals and international conferences, including ACM SIGMOD, VLDB, AAAI, the IEEE transactions on Γ and Engineering, the IEEE Transactions on Intelligent Transportation Systems, and Information Sciences. He was TPC member of several prestige conferences, and he chaired conferences in VLDB 2018, VLDB 2017, ICDM 2015, and APWEB-WAIM 2017 on resultity analysis.

ILDAR NURGALIEV received the M.Sc. degree in Data Science from the Innopolis university in 2017, Tatarstan, Russia. Currently, he is a PhD student in Shenguen Institutes of Advanced Technology, Chinese Academy of Sciences, Chenzhen, China. He was a student at CERN OpenLab in 2013, Geneva, Switzerland. His research interests include bloc. Chain and social network analysis.

MUHAMMAD MUZAMMAL is an associate professor at the Department of Computer Science, Bahria University, Islamabad, Pakist in, a visiting associate professor under CAS President's International Fellowship Initiative (PIFI) at the Centre of Big Mone Intelligence, Shenzhen Institutes of Advance Technology (LTAT), Chinese Academy of Sciences (CAS), Shenzhen, and a Vice Lirector of Guangdong Provincial R&D Centre of Blockchain

and Distributed of Security, Guangdong, China. He received the PhD degree from University of Licesco UK, in 2012. Before, that he was a software analyst at LMKR. He received he mas er's and bachelor's degrees from FAST-NU, Pakistan, and IIUI, Pakistan, in 2007 and 2005, respectively. His research interests are in large scale data mining ir cluding algorithm design and mobility data mining. Recently, he is interested in blocked ain technology with a focus on decentralized systems and mining.

CHRISTIAN S. JENSEN is a Professor of Computer Science at Aarhus University, Denmark, and he was previously at Aalborg University for two decades. He recently spent a 1-year sabbatical at Google Inc., Mountain View. His research concerns data management and data-intensive systems, and its focus is on amporal and spatio-temporal data management. Christian is at ACM and an IEEE fellow, and he is a member of the Royal Davin Academy of

Sciences and Letters and the Danish Academy of Technical Science. He has received several national and international awards for his research. He is currently vice-chair of ACM SIGMOD and an editor-in-chief of The VLDB Journal.

JIANPING FAN, since 2006, served a Director of Shenzhen Institutes of Advanced Technology, CAL. His research interests include high performance computing Grid computing, and computer architecture. He designed and developed a series supercomputer including Dawning J. Dawning 1000, Dawning 3000 and Dawning 4000. He has been a Principal Investigator of 21 projects funded by both government and industries. Based on his

research work, he has published more than 118 papers and acquired 23 pending or issued patents. He has received many award, such as outstanding award of CAS science and technology progress, first price of Beijing science and technology progress, the outstanding young scientist of CAS, and the national talent of the Century talent program. He has actively participated in various professional activities. He served as editor of journal of integration technology, joint professional activities. He served as editor of journal of integration technology, joint professional activities. Advisor of 11th five years science and technology development play of ministry of information industry, general chair of HPC China2007,GCC2008,PAKL 2011, CNCC 2011, the The mayor award of Shenzhen 2013, Fellow of CCF 2014. Vice president of the Institute of talent research 2016.

Highlights

The highlights of this work are as follows:

- One of the first attempts to formalize the spatio- emporal blockchain query processing
- A note on the limitations in current blockchair syste as and a novel solution for spatio-temporal query processing on blockchair.
- Introduction of a block-DAG based novel index traversal algorithm, TGS-BSI, to handle spatio-temporal queries on a block-DAG.
- A detailed experimental evaluation to comor strate the effectiveness of the solution
