# Estimation of Regional Transition Probabilities for Spatial Dynamic Microsimulations from Survey Data Lacking in Regional Detail 

Jan Pablo Burgard, Joscha Krause, Simon Schmaus<br>Department of Economic and Social Statistics, Trier University

#### Abstract

Spatial dynamic microsimulations allow for the multivariate analysis of complex socioeconomic systems with geographic segmentation. For this, a synthetic replica of the system as base population is stochastically projected into future periods. Thereby, the projection is based on micro-level transition probabilities. They need to accurately represent the characteristic dynamics of the system to allow for reliable simulation outcomes. In practice, transition probabilities are unknown and must be estimated from suitable survey data. This can be challenging when the characteristic dynamics vary locally. Survey data often lacks in regional detail due to confidentiality restrictions and limited sampling resources. In that case, transition probability estimates may misrepresent local dynamics as a result of insufficient local observations and coverage problems. The simulation process then fails to provide an authentic evolution. We present two transition probability estimation techniques that account for regional heterogeneity when the survey data lacks in regional detail. Using methods of constrained optimization and ex-post alignment, we show that local micro level transition dynamics can be accurately recovered from aggregated regional benchmarks. The techniques are compared in theory and subsequently tested in a simulation study.

Keywords: Constrained Maximum Likelihood, Logit Scaling, Spatiotemporal Modelling, Regional Benchmark

## 1 Introduction

Microsimulations are powerful tools for the multivariate analysis of complex systems, such as economic markets or medical care infrastructures. They differ from the more established macrosimulations in terms of the objects that are considered in the simulation process. While in macrosimulations the behaviour of aggregated system-intrinsic entities is modelled, microsimulations target the smallest entities of the system (units) directly. This allows for the investigation of multidimensional interactions and nonlinear dependencies within the system that cannot be studied by macrosimulations. Examples for microsimulation models can be found in Klevmarken (2010), Lawson (2011), O'Donoghue et al. (2011), as well as Markham et al. (2017).

Microsimulations are often conducted according to a basic procedure. First, a base population as synthetic replica of the system of interest is constructed. In practice, this may be either artificially constructed data, or real-world observations from administrative records and surveys (Li and O'Donoghue, 2014). Next, multiple parameters that characterize the system in its initial state are altered in scenarios. Thereby, the alterations are designed to target properties of the system in the light of the research objectives. The effects of the alterations are then projected into future periods and construct individual branches in the system's evolution. After a given number of periods (simulation horizon), the branches are compared and give insights on important dynamics and interdependencies within the system (Burgard et al., 2019).

There are different types of microsimulations. They mainly differ in the manner in which the mentioned alterations are projected. An important distinction is between static and dynamic microsimulations (Li and O'Donoghue, 2013). Static microsimulations are characterized by the constancy of unit characteristics over time. When constructing the synthetic replica, every unit is provided with a set of characteristics that determines its behaviour and interaction with other units. In static microsimulations, these characteristics don't change over the simulation horizon. Only specific simulation inputs are altered, depending on the research objectives. Examples for static microsimulation models can be found in Peichl et al. (2010), as well as Sutherland and Figari (2013).

Dynamic microsimulations, on the other hand, are characterized by stochastic changes of unit characteristics (state transitions) over time. The evolution of units, as well as their interactions, are determined by frequently changing base datasets. Examples for dynamic microsimulation models can be found in O'Donoghue et al. (2009), as well as Fialka et al. (2011). If the dynamic microsimulation is time-discrete, state transitions can only appear
periodically at distinct points of time. If the simulation is time-continuous, they can appear at any given time and thus are modelled via survival functions (Willekens, 2009).

In the following, we focus on dynamic microsimulations with discrete time. More precisely, we look at dynamic microsimulation models in socio-economic research where primarily polytomous variables are of interest. This conceptual delimitation differentiates the topic from other fields where corresponding simulation methods are also relevant, such as particle physics or cancer research. In order to initialize a corresponding simulation, every unit in the synthetic replica must be provided with an individual set of transition probabilities. They define the conditional likelihood of a state transition for some unit characteristic given its current state as well as other characteristics. The probabilities constitute stochastic processes within the synthetic replica over the simulation horizon. Thereby, they need to represent elementary dynamics of the real system as genuine as possible to obtain valid simulation results. Transition probabilities are usually unknown in practice and thus must be estimated. This is done via parametric statistical models using suitable survey data.

Transition probability estimation can be challenging if the system of interest is geographically segmented into regions. In the literature, a microsimulation that accounts for regional data structures is often referred to a small area or spatial microsimulation (Rahman et al., 2010; Rahman and Harding, 2016; Tanton et al., 2018). In such a setting, there may be heterogeneity across regions with respect to transition dynamics. The statistical approach used for transition probability estimation must explicitly account for these local differences in order to adequately reflect the system's dynamics. However, in practice, we often encounter the problem that the survey data used for transition probability estimation lacks in regional detail. Due to confidentiality restrictions, regional identifiers that would allow for spatial localization of the sample elements may be censored. Regional heterogeneity in transition dynamics then cannot be observed as spatial aggregates are indistinguishable.

Further, even if regional identifiers are available, the majority of survey samples often contain only a few observations per region due to limited resources. In that case, observed regional transition frequencies may be inaccurate or even biased as a result of coverage problems. Ignoring these issues may cause only small deviations in the initial phase of the simulation. But due to the complex interactions between units, the inaccuracies accumulate and self-reinforce over the simulation horizon. Hence, local transition dynamics are misrepresented over time and the simulation fails to provide an authentic evolution of the synthetic replica with respect to the real system. The simulation outcomes are subsequently not reliable anymore (Chin and Harding, 2006; Tanton, 2014). Accordingly, if the survey
data used for transition probability estimation lacks in regional detail, methodological adjustments are required.

In this paper, we investigate two extensions of the multinomial logit model (McCullagh and Nelder, 1989; Greene, 2002) to recover local heterogeneity in transition dynamics when the primary database lacks in regional detail. The extensions are addressed in the context of spatial dynamic microsimulations where it is required to provide micro-level transition probabilities for every unit of the synthetic replica. We consider a situation in which external benchmarks on regional transition dynamics are available (e.g. from census data). The general idea is to incorporate this regional information in the multinomial logit model and modify the estimation process such that resulting micro level probability estimates are consistent with the benchmarks when aggregated. Benchmark consistency can be either perfect in the sense that all values are reproduced exactly, or approximately by allowing for deviations in terms of box constraints. With this, we seek to recover the previously unobservable regional heterogeneity in transition dynamics on the micro level.

The first extension is called logit scaling and was originally proposed by Stephensen (2016). It is an ex-post alignment method based on iterative proportional fitting (Bishop et al., 1970). After the initial estimation process, the transition probability estimates obtained from multinomial logit are adjusted sequentially until they are consistent with the external benchmarks. Thereby, the Kullback-Leibler divergence between original and adjusted estimates is minimized. The second extension was developed in this study and draws from constrained maximum likelihood theory (e.g. Dong and Wets, 2000; Chatterjee et al., 2016). The external regional benchmarks are used to directly modify parameter estimation in the multinomial logit model. This done by imposing box constraints on model predictions and thus transition probability estimates. Constrained parameter estimation is performed by a sequential quadratic programming approach (Kraft, 1994).

The methods are first described and discussed in theory. Afterwards, they are applied and tested under different settings in an extended simulation study. For this, survey data from the German Microcensus 2013. We find that the inclusion of aggregated regional benchmarks allows for the recovery of local micro level transition dynamics despite a lack in regional detail. The remainder of the paper is organized as follows. In Chapter 2, the required technical framework and the multinomial logit model are described. In Chapter 3, the two extensions to the model are presented. Chapter 4 contains the simulation study. Chapter 5 closes with some conclusive remarks.

## 2 Basic Methodology

### 2.1 Technical Framework

We introduce a technical framework that is required to describe the estimation methods within this paper. For simplicity, assume that the system of interest is an arbitrary population of individuals. In the following, three representations of this population are considered. First, let $\mathcal{U}$ denote the real population that contains $|\mathcal{U}|=N$ individuals. It marks the system that the researcher seeks to analyze. With respect to the spatial segmentation discussed in Chapter 1, assume that $\mathcal{U}=\bigcup_{r=1}^{R} \mathcal{U}_{r}$ consists of $R$ areas indexed by $r=1, \ldots, R$ with $\mathcal{U}_{r}, \mathcal{U}_{v} \in \mathcal{U}$ pairwise disjoint for $r \neq v$. The number of individuals per area is $\left|\mathcal{U}_{r}\right|=N_{r}$ with $\sum_{r=1}^{R} N_{r}=N$. Second, denote $\tilde{\mathcal{U}}$ as the synthetic replica of $\mathcal{U}$ containing $|\tilde{\mathcal{U}}|=\tilde{N}$ units indexed by $u=1, \ldots, \tilde{N}$. It is projected over simulation horizon $\mathcal{S}=\{1, \ldots, S\}$ with simulation periods $s$ to provide essential insights on $\mathcal{U}$. Note that formally $\mathcal{S}$ is an index set. For the projection, every $u \in \tilde{\mathcal{U}}$ must be associated with a set of transition probabilities that accurately represent relevant dynamics of $\mathcal{U}$. Since $\tilde{\mathcal{U}}$ is designed to be a close-toreality representation of $\mathcal{U}$, it must reflect the spatial segmentation of the real population. Accordingly, we have $\tilde{\mathcal{U}}=\bigcup_{r=1}^{R} \tilde{\mathcal{U}}_{r}$ with $\tilde{\mathcal{U}}_{r}, \tilde{\mathcal{U}}_{v} \in \tilde{\mathcal{U}}$ pairwise disjoint for $r \neq v$. The number of units per synthetic area is $\left|\tilde{\mathcal{U}}_{r}\right|=\tilde{N}_{r}$ with $\sum_{r=1}^{R} \tilde{N}_{r}=\tilde{N}$. And third, let $\mathcal{D} \subset \mathcal{U}$ be a survey sample that is drawn from $\mathcal{U}$ with observations of $|\mathcal{D}|=n$ unique individuals for $T$ time periods, where $i=1, \ldots, n$ and $t=1, \ldots, T$. It marks the data basis from which transition probability estimates are derived in order to apply them to $\tilde{\mathcal{U}}$. In an ideal sampling situation, $\mathcal{D}$ contains area-specific subsamples $\mathcal{D}_{r} \subset \mathcal{U}_{r}$ with $\left|\mathcal{D}_{r}\right|=n_{r}$ and $n_{r}$ sufficiently large for all $r$. In practice, the regional index $r$ might be unknown, or $n_{r}$ may be small.

As stated previously, every unit is associated with a set of characteristics that determines its behaviour and interaction with other units. Since we consider dynamic microsimulations, the unit-specific values of this set may change in any $s \in \mathcal{S}$. Let $Y: \mathcal{Y} \rightarrow \mathbf{E}$ be a polytomous random variable representing a unit characteristic for which transition probabilities are desired. It can have a finite number $J$ of possible outcomes that form the state space $\mathcal{Y}=\left\{Y_{1}, \ldots, Y_{J}\right\}$ whose elements $Y_{j}$ are unordered, mutually exclusive, and indexed by $j=1, \ldots, J . \mathbf{E}$ is some measurable space. Let $\mathcal{F}$ be the $\sigma$-algebra of subsets of $\mathcal{Y}$ and $P: \mathcal{F} \rightarrow[0,1]$ be a probability measure. In order to understand the following definitions, we briefly recall the concept of discrete stochastic processes.

Definition 1 Let $(\mathcal{Y}, \mathcal{F}, P)$ be a probability space, $\mathbf{E}$ be a measurable space, and $\mathcal{S}=\mathbb{Z}^{+}$ be an index set. Suppose that for every $s \in \mathcal{S}$, there is a $Y^{(s)}: \mathcal{Y} \rightarrow \mathbf{E}$ defined on $(\mathcal{Y}, \mathcal{F}, P)$.

Then, the function $Y: \mathcal{S} \times \mathcal{Y} \rightarrow \mathbf{E}$ is called discrete stochastic process.
Thereafter, we need to distinguish between the concepts of state occurrence and state transition for the estimation methods in the subsequent chapters.

Definition 2 Let $y_{u r}^{(s)}$ be the realized value of $Y$ for some $u \in \tilde{\mathcal{U}}_{r}$ in $s \in \mathcal{S}$. A state occurrence is the outcome of a discrete stochastic process where $y_{u r}^{(s)}=Y_{j}$ for a given $Y_{j} \in \mathcal{Y}$. Its probability is given by $\pi_{u r}^{(s) j}:=P\left(y_{u r}^{(s)}=Y_{j}\right)$.

Definition 3 A state transition is the outcome of a discrete stochastic process where $y_{u r}^{(s)}=$ $Y_{j}$ and $y_{u r}^{(s+1)}=Y_{k}$ with $Y_{j}, Y_{k} \in \mathcal{Y}$ and $Y_{j} \neq Y_{k}$ for $u \in \tilde{\mathcal{U}}_{r}$ and $s \in \mathcal{S}$. Its probability is given by $\pi_{u r}^{(s+1) j k}:=P\left(y_{u r}^{(s+1)}=Y_{k} \mid y_{u r}^{(s)}=Y_{j}\right)$.

Please note that $Y_{j}=Y_{k}$ is also allowed in the simulation process. However, we don't refer to it as a state transition since the unit-specific value of $Y$ has not changed between periods. Let $\mathbf{X}=\left(X_{1}, \ldots, X_{p}\right)$ be a set of random variables with $X_{\iota}: \Omega \rightarrow \mathbb{R}$ for $\iota=1, \ldots, p$ that represent other unit characteristics statistically related to $Y$. Denote the value of $\mathbf{X}$ for $u \in \tilde{\mathcal{U}}_{r}$ in simulation period $s$ as $\mathbf{x}_{u r}^{(s)}$. The conditional probability of a state transition from $Y_{j}$ to $Y_{k}$ for $u \in \tilde{\mathcal{U}}_{r}$ in $s+1$ is defined according to:

$$
\begin{equation*}
\pi_{u r}^{(s+1) j k}\left(y_{u r}^{(s)}, \mathbf{x}_{u r}^{(s+1)}, s\right):=P\left(y_{u r}^{s+1}=Y_{k} \mid y_{u r}^{(s)}=Y_{j}, \mathbf{X}=\mathbf{x}_{u r}^{(s+1)}, \mathcal{S}=s\right), \tag{1}
\end{equation*}
$$

where $Y_{j}, Y_{k} \in \mathcal{Y}$ and $0 \leq \pi_{u r}^{(s+1) j k}\left(y_{u r}^{(s)}, \mathbf{x}_{u r}^{(s+1)}, s\right) \leq 1$. For notational convenience, assume that it is sufficient to only consider the last period when modelling the state transition. Further, for simplicity, assume that the conditional transition probabilities are time-invariant and only vary across units as well as simulation scenarios. Hence,

$$
\begin{equation*}
\pi_{u r}^{(s+1) j k}\left(y_{u r}^{(s)}, \mathbf{x}_{u r}^{(s+1)}, s\right)=\pi_{u r}^{(s+1) j k}\left(y_{u r}^{(s)}, \mathbf{x}_{u r}^{(s+1)}\right) . \tag{2}
\end{equation*}
$$

However, the methods discussed in this paper can be adjusted to provide conditional timevariant transition probabilities, e.g. by including time variable in $\mathbf{X}$. Note that $\pi_{u r}^{(s+1) k}$ is driven by the last state $y_{u r}^{(s)}$ and the additional characteristics $\mathbf{x}_{u r}^{(s+1)}$. On the contrary, $\pi_{u r}^{(s+1) j k}$ varies exclusively with $\mathbf{x}_{u r}^{(s+1)}$. Generally, in the light of all simulation periods and potential states, transition dynamics can be summarized in a right stochastic matrix

$$
\mathbf{P}_{u r}=\left(\begin{array}{cccc}
\pi_{u r}^{(s+1) 11}\left(y_{u r}^{(s)}, \mathbf{x}_{u r}^{(s+1)}\right) & \pi_{u r}^{(s+1) 12}\left(y_{u r}^{s}, \mathbf{x}_{u r}^{s+1}\right) & \ldots & \pi_{u}^{(s+1) 1 J}\left(y_{u r}^{(s)}, \mathbf{x}_{u r}^{(s+1)}\right)  \tag{3}\\
\vdots & \vdots & \ddots & \\
\pi_{u r}^{(s+1) J 1}\left(y_{u r}^{(s)}, \mathbf{x}_{u r}^{(s+1)}\right) & \pi_{u r}^{(s+1) J 2}\left(y_{u r}^{s}, \mathbf{x}_{u r}^{s+1}\right) & \ldots & \pi_{u r}^{(s+1) J J}\left(y_{u r}^{(s)}, \mathbf{x}_{u r}^{(s+1)}\right)
\end{array}\right),
$$

where $\sum_{k=1}^{J} \pi_{u r}^{(s+1) j k}\left(y_{u r}^{(s)}, \mathbf{x}_{u r}^{(s+1)}\right)=1$. However, note that for a given $u \in \tilde{\mathcal{U}}_{r}$ with known $y_{u r}^{(s)}=Y_{j}$ and $\mathbf{x}_{u r}^{(s+1)}$, we have $\pi_{u r}^{(s+1) j k}=\pi_{u r}^{(s+1) k}$. In that case, the probabilities of state occurrences are equal to the state transition probabilities. Subsequently, they can be summarized for a given simulation period $s+1$ in a vector $\boldsymbol{\pi}_{u r}^{(s+1)}=\left(\pi_{u r}^{(s+1) j 1}, \ldots, \pi_{u r}^{(s+1) j J}\right)$. Next, the concept of regional heterogeneity in transition dynamics in our setting is introduced.

Definition 4 Let $\pi_{u r}^{(s+1) j k}=P\left(y_{u r}^{s+1}=Y_{k} \mid y_{u r}^{(s)}=Y_{j}\right)$ with $Y_{j}, Y_{k} \in \mathcal{Y}$ and $s \in \mathcal{S}$. Regional heterogeneity in transition dynamics is a situation where $\tilde{N}_{r}^{-1} \sum_{u \in \tilde{\mathcal{U}}_{r}} \pi_{u r}^{(s+1) j k} \neq$ $\tilde{N}_{q}^{-1} \sum_{u \in \tilde{\mathcal{U}}_{q}} \pi_{u q}^{(s+1) j k}$ for $\tilde{\mathcal{U}}_{r}, \tilde{\mathcal{U}}_{q} \in \tilde{\mathcal{U}}$ and $r \neq q$.

Accordingly, the term corresponds to regional differences in the mean of probabilities for a given state transition. Within this paper, we provide an overview of methods to obtain transition probability estimates $\widehat{\pi}_{u r}^{(s+1) j k}$ from the sample elements $i \in \mathcal{D}$ to obtain $\boldsymbol{\pi}_{u r}^{(s+1)}$ for every $u \in \tilde{\mathcal{U}}$ and $s=1, \ldots, S-1$ under regional heterogeneity. It is argued that if $\mathcal{D}$ does not allow for the empirical observation of local transition dynamics, the resulting estimates $\widehat{\pi}_{u r}^{(s+1) j k}$ are inaccurate with respect to transition dynamics in $\mathcal{U}_{r}$.

### 2.2 Multinomial Logit

We use the well-established multinomial logit model (McCullagh and Nelder, 1989; Greene, 2002) as basic methodology for transition probability estimation. All descriptions are with respect to the survey-based micro data obtained from $\mathcal{D}$. Assume that the regional index $r$ is not observed for the sample elements. Let the pair $(Y, \mathbf{X})$ be observed for the sampled individuals $i \in \mathcal{D}$ with time- and individual-specific values $\left(y_{i}^{(t)}, \mathbf{x}_{i}^{(t)}\right)$ in $t$. Let $\pi_{i}^{(t) j}=P\left(y_{i}^{(t)}=Y_{j}\right)$ be the occurrence probability of $Y_{j}$ for individual $i$ in $t$ with $\sum_{j=1}^{J} \pi_{i}^{(t) j}=1$. Define $Y_{i}^{(t) j}$ as a binary random variable that takes value 1 , if $y_{i}^{(t)}=Y_{j}$, and 0 else. Its realization is denoted by $y_{i}^{(t) j}$, with $\sum_{j=1}^{J} y_{i r}^{(t) j}=1$. The probability distribution of $y_{i}^{(t) j}$ is given by

$$
\begin{equation*}
P\left(Y_{i}^{(t) 1}=y_{i}^{(t) 1}, \ldots, Y_{i}^{(t) J}=y_{i}^{(t) J}\right)=\binom{1}{y_{i}^{(t) 1}, \ldots, y_{i}^{(t) J}}\left(\pi_{i}^{(t) 1}\right)^{y_{i}^{(t) 1}} \cdot \ldots \cdot\left(\pi_{i}^{(t) J}\right)^{y_{i}^{(t) J}} . \tag{4}
\end{equation*}
$$

In order to model the probabilities $\pi_{i}^{(t) j}$ dependent on the time- and individual-specific covariate values $\mathbf{x}_{i}^{(t)}$ as well as the last state value $y_{i}^{(t-1)}$, it is common to determine one state as reference outcome. Since our basic setting is to estimate the probability of a transition from $Y_{j}$ to $Y_{k}$, we use $Y_{j}$ as reference. Recall from Chapter 2.1 that the probability of occurrence is equal to the transition probability when conditioned on the previous period. The log-odds for all feasible states relative to this reference outcome are calculated as a
linear function of the predictors:

$$
\begin{equation*}
\eta_{i}^{(t) k}=\eta_{i}^{(t) k}\left(\alpha_{k}, \boldsymbol{\beta}_{k}, \boldsymbol{\gamma}_{k}\right)=\log \left(\frac{\pi_{i}^{(t) k}}{\pi_{i}^{(t) j}}\right)=\alpha_{k}+\left(\mathbf{x}_{i}^{(t)}\right)^{\prime} \boldsymbol{\beta}_{k}+\left(\mathbf{y}_{i}^{(t-1)}\right)^{\prime} \boldsymbol{\gamma}_{k} \tag{5}
\end{equation*}
$$

for $k \neq j$, where $\alpha_{k} \in \mathbb{R}$ is a state-specific constant, $\boldsymbol{\beta}_{k} \in \mathbb{R}^{p}$ is the vector of regression coefficients associated with $\mathbf{x}_{i}^{(t+1)}$ and $\gamma_{k} \in \mathbb{R}^{J}$ is a coefficient vector quantifying the influence of $\mathbf{y}_{i}^{(t-1)}=\left(y_{i}^{(t-1) 1}, \ldots, y_{i}^{(t-1) J}\right)$. Note that $\boldsymbol{\beta}_{k}$ also varies across log-odds. One obtains a set of $J-1$ independent binary regression models, in which all other states are separately regressed against the reference outcome. From (5), the individual probabilities can be obtained from (Böhning, 1992)

$$
\begin{equation*}
\pi_{i}^{(t) k}=\frac{\exp \left(\eta_{i}^{(t) k}\left(\alpha_{k}, \boldsymbol{\beta}_{k}, \boldsymbol{\gamma}_{k}\right)\right)}{1+\sum_{l \in\{1, \ldots, J\} \backslash j}^{J} \exp \left[\eta_{i}^{(t) l}\left(\alpha_{l}, \boldsymbol{\beta}_{l}, \boldsymbol{\gamma}_{l}\right)\right]} \tag{6}
\end{equation*}
$$

for $k \neq j$, and for $k=j$

$$
\begin{equation*}
\pi_{i}^{(t) k}=\frac{1}{1+\sum_{l \in\{1, \ldots, J\} \backslash j}^{J} \exp \left[\eta_{i}^{(t) l}\left(\alpha_{l}, \boldsymbol{\beta}_{l}, \boldsymbol{\gamma}_{l}\right]\right)} \tag{7}
\end{equation*}
$$

The parameters of the multinomial logit model are then estimated via maximum likelihood. Define $\boldsymbol{\theta}_{k}:=\left(\alpha_{k}, \boldsymbol{\beta}_{k}, \boldsymbol{\gamma}_{k}\right)$. For notational convenience, we display the log-likelihood function for a single individual $i \in \mathcal{D}$, which is given by (Böhning, 1992)

$$
\begin{align*}
l_{i}^{(t)}\left(\boldsymbol{\theta}_{1}, \ldots, \boldsymbol{\theta}_{J}\right) & =\log \left(\prod_{l=1}^{J}\left(\pi_{i}^{(t) l}\right)^{y_{i}^{(t) l}}\right) \\
& =\sum_{l \in\{1, \ldots, J\} \backslash j}^{J} y_{i}^{(t) l} \eta_{i}^{(t) l}\left(\boldsymbol{\theta}_{l}\right)-\log \left(1+\sum_{l \in\{1, \ldots, J\} \backslash j}^{J} \exp \left[\eta_{i}^{(t) l}\left(\boldsymbol{\theta}_{l}\right)\right]\right) . \tag{8}
\end{align*}
$$

Assuming the sample observations are independent, model parameter estimates are obtained from minimizing the sum of negative individual log-likelihoods

$$
\begin{equation*}
\left(\widehat{\boldsymbol{\theta}}_{1}, \ldots, \widehat{\boldsymbol{\theta}}_{J}\right)=\underset{\boldsymbol{\theta}_{1}, \ldots, \boldsymbol{\theta}_{J}}{\operatorname{argmin}}\left\{-\left[\sum_{t=2}^{T} \sum_{i \in \mathcal{D}} l_{i}^{(t)}\left(\boldsymbol{\theta}_{1}, \ldots, \boldsymbol{\theta}_{J}\right)\right]\right\} . \tag{9}
\end{equation*}
$$

Maximization can be performed by various numerical procedures, such as generalized iterative scaling (Darroch and Ratcliff, 1972), iteratively reweighted least squares (Bishop, 2006), or the Newton-Raphson (Böhning, 1992). Theoretically, once the model parameter estimates are obtained from $\mathcal{D}$, they can be used to estimate $\widehat{\boldsymbol{\pi}}_{u r}^{(s+1)}$ for all $u \in \tilde{\mathcal{U}}_{r}$. This is
then achieved by combining them with the unit-specific values $\left(y_{u r}^{(s)}, \mathbf{x}_{u r}^{(s+1)}\right)$ according to

$$
\begin{equation*}
\widehat{\pi}_{u r}^{(s+1) j k}=\widehat{\pi}_{u r}^{(s+1) k}=\frac{\exp \left[\widehat{\alpha}_{k}+\left(\mathbf{x}_{u r}^{(s+1)}\right)^{\prime} \widehat{\boldsymbol{\beta}}_{k}+\widehat{\gamma}_{k}^{j}\right]}{1+\sum_{l \in\{1, \ldots, J\} \backslash j}^{J} \exp \left[\widehat{\alpha}_{l}+\left(\mathbf{x}_{u r}^{(s+1)}\right)^{\prime} \widehat{\boldsymbol{\beta}}_{l}+\widehat{\gamma}_{l}^{j}\right]} \quad \forall k=1, \ldots, J, \tag{10}
\end{equation*}
$$

where $\widehat{\gamma}_{k}^{j} \in \widehat{\gamma}_{k}$ is the coefficient resulting from $y_{u r}^{(s)}=Y_{j}$. However, we argue that if the survey data $\mathcal{D}$ does not allow for the observation of regional heterogeneity according to Definition 4, the resulting transition probability estimates $\widehat{\pi}_{u r}^{(s+1) j k}$ for a given $u \in \tilde{\mathcal{U}}_{r}$ misrepresent the local transition dynamics in $\mathcal{U}_{r}$.

## 3 Extensions for Regional Heterogeneity

We now show how to account for regional heterogeneity despite $\mathcal{D}$ lacking in regional detail. For this, assume that benchmarks

$$
\tau_{r}^{(t) k}:=\sum_{i \in \mathcal{U}_{r}} \sum_{k=1}^{J} y_{i r}^{(t) k} \quad \text { with } \quad y_{i r}^{(t) k}= \begin{cases}1 & \text { if } y_{i r}^{(t)}=Y_{k}  \tag{11}\\ 0 & \text { else }\end{cases}
$$

are known for all $Y_{k} \in \mathcal{Y}$ as well as all $r=1, \ldots, R$ and some $t$ corresponding to $s+1$. At this point, we postpone the discussion whether corresponding knowledge is realistic and pick it up again in Section 5. Due to the lack in regional detail in $\mathcal{D}$ and the consequences for the resulting transition probability estimates (10), it may be that

$$
\begin{equation*}
\Delta_{r}^{(s) k}:=\left|\sum_{u \in \tilde{\mathcal{U}}_{r}} \sum_{j=1}^{J} \widehat{\pi}_{u r}^{(s+1) j k}-\tau_{r}^{(t) k}\right|>\epsilon_{r}^{k}, \tag{12}
\end{equation*}
$$

for some $\tilde{\mathcal{U}}_{r} \in \tilde{\mathcal{U}}$ and $Y_{k} \in \mathcal{Y} . \epsilon_{r}^{k} \in \mathbb{R}_{\geq 0}$ denotes a predefined critical deviation value for category $Y_{k}$ resulting from box constraints with respect to $\mathcal{U}_{r}$. To ensure consistency with respect to the regional benchmarks, we would like to find new sets $\left\{\widehat{\boldsymbol{\pi}}_{1 r}^{(s+1) *}, \ldots, \widehat{\boldsymbol{\pi}}_{N_{r} r}^{(s+1) *}\right\}$ that satisfy the system of inequality constraints

$$
\begin{array}{cccc}
\Delta_{1}^{(s) 1} \leq \epsilon_{1}^{1}, & \Delta_{1}^{(s) 2} \leq \epsilon_{1}^{2}, & \ldots & \Delta_{1}^{(s) J} \leq \epsilon_{1}^{J}, \\
\Delta_{2}^{(s) 1} \leq \epsilon_{2}^{1}, & \Delta_{2}^{(s) 2} \leq \epsilon_{2}^{2}, & \ldots & \Delta_{2}^{(s) J} \leq \epsilon_{2}^{J}, \\
\vdots & \vdots & \ddots &  \tag{13}\\
\Delta_{R}^{(s) 1} \leq \epsilon_{R}^{1}, & \Delta_{R}^{(s) 2} \leq \epsilon_{R}^{2}, & \ldots & \Delta_{R}^{(s) J} \leq \epsilon_{R}^{J} .
\end{array}
$$

For this, the methodology for transition probability estimation must be extended. Hereafter, two corresponding extensions are described.

### 3.1 Logit Scaling

The first extension is logit scaling and has been proposed by Li and O'Donoghue (2014), as well as Stephensen (2016). It is a simple multivariate ex-post alignment method that manipulates the estimated probability distribution resulting from the multinomial logit model. For some $\tilde{\mathcal{U}}_{r} \in \tilde{\mathcal{U}}$ and $Y_{j} \in \mathcal{Y}$, this is achieved by sequentially adjusting the mean

$$
\begin{equation*}
q_{u r}^{(s+1) j}:=\frac{1}{\tilde{N}_{r}} \sum_{u \in \tilde{\mathcal{U}}_{r}} \widehat{\pi}_{u r}^{(s+1) j} \tag{14}
\end{equation*}
$$

until the regional constraint is satisfied. Thereby, the adjustment is performed via iterative proportional fitting Bishop et al. (1970). Hereafter, we sketch the methodology based on Stephensen (2016). Let $\mathcal{Q}_{r}=\left\{q_{u r}^{(s+1) j} \mid u=1, \ldots, \tilde{N}_{r} ; j=1, \ldots, J\right\}$ be the joint discrete probability distribution of states and units for $\tilde{\mathcal{U}}_{r}$. Denote $\mathcal{Q}_{r}^{[0]}$ as the initial probability distribution estimated from the multinomial logit model in Chapter 2.2. On that note, let $q_{u r}^{[0](s+1) j}$ and $\widehat{\pi}_{u r}^{[0](s+1) j}$ be the initial versions of $q_{u r}^{(s+1) j}$ and $\widehat{\pi}_{u r}^{(s+1) j}$ after estimating the multinomial logit model. The objective is to find a set of new probability distributions $\left\{\mathcal{Q}_{1}^{*}, \ldots, \mathcal{Q}_{R}^{*}\right\}$ that satisfy (13) while restricting the adjustment of the $\widehat{\pi}_{u r}^{[0](s+1) j}$ for all $Y_{j} \in$ $\mathcal{Y}$ within $\tilde{\mathcal{U}}_{r} \in \tilde{\mathcal{U}}$ to a minimum. This is achieved by minimizing the Kullback-Leibler divergence between $\mathcal{Q}_{r}^{[0]}$ and $\mathcal{Q}_{r}$

$$
\begin{align*}
D_{r}^{K L}\left(\mathcal{Q}_{r} \| \mathcal{Q}_{r}^{[0]}\right) & =\sum_{u \in \tilde{\mathcal{U}}_{r}} \sum_{j=1}^{J} q_{u r}^{(s+1) j} \log \left(\frac{q_{u r}^{(s+1) j}}{q_{u r}^{[0](s+1) j}}\right) \\
& =\frac{1}{N_{r}} \sum_{u \in \tilde{\mathcal{U}}_{r}} \sum_{j=1}^{J} \widehat{\pi}_{u r}^{(s+1) j} \log \left(\frac{\widehat{\pi}_{u r}^{(s+1) j}}{\widehat{\pi}_{u r}^{[0](s+1) j}}\right) \tag{15}
\end{align*}
$$

subject to the system of inequality constraints. Hence, for some $\tilde{\mathcal{U}}_{r} \in \tilde{\mathcal{U}}$, we obtain the minimization problem

$$
\begin{equation*}
\min _{\hat{\pi}_{1 r}^{(s+1)}, \ldots, \hat{\pi}_{N r r}^{(s+1)}}\left\{D_{r}^{K L}\left(\mathcal{Q}_{r} \| \mathcal{Q}_{r}^{[0]}\right)\right\} \quad \text { s.t. } \quad \Delta_{r}^{(s) 1} \leq \epsilon_{r}^{1}, \ldots, \Delta_{r}^{(s) J} \leq \epsilon_{r}^{J} . \tag{16}
\end{equation*}
$$

Solving it for $r=1, \ldots, R$ individually then obtains sets $\left(\widehat{\boldsymbol{\pi}}_{1 r}^{(s+1) *}, \ldots, \widehat{\boldsymbol{\pi}}_{N_{r} r}^{(s+1) *}\right)$ with the desired properties. Stephensen (2016) showed that the minimization problem can be solved by a bi-proportionate scaling algorithm Define matrices $\widehat{\boldsymbol{\Pi}}_{r}^{[0](s+1)}:=\left(\widehat{\boldsymbol{\pi}}_{1 r}^{[0](s+1)}, \ldots, \widehat{\boldsymbol{\pi}}_{\tilde{N}_{r} r}^{[0](s+1)}\right)^{\prime}$
for all $\tilde{\mathcal{U}}_{r} \in \tilde{\mathcal{U}}$. Let $\ell=1,2, \ldots$ be the index of iterations. The algorithm is performed on $\widehat{\boldsymbol{\Pi}}_{1}^{(s+1)}, \ldots, \widehat{\boldsymbol{\Pi}}_{R}^{(s+1)}$ as described hereafter.

```
Algorithm 1 Bi-Proportionate Scaling
    1: set \(\widehat{\pi}_{u r}^{[\ell](s+1) j}=\widehat{\pi}_{u r}^{[0](s+1) j}\) for \(j=1, \ldots, J\) and \(r=1, \ldots, R\)
    2: for \(r=1, \ldots, R\) do
        while \(\Delta_{r}^{(s) j}>\epsilon_{r}^{j}\) for any \(Y_{j} \in \mathcal{Y}\) do
            scale columns with \(\omega_{k}^{[\ell]}\) : set \(\widehat{\pi}_{u r}^{[\ell+1](s+1) j}=\omega_{k}^{[\ell]} \widehat{\pi}_{u r}^{[\ell](s+1) j}\) such that
                \(\left|\sum_{u \in \tilde{\mathcal{U}}_{r}} \widehat{\pi}_{u r}^{[\ell+1](s+1) j}-\tau_{r}^{(t) j}\right|<\epsilon_{r}^{k}\)
5: \(\quad\) scale rows with \(\zeta_{u r}^{[\ell]}:\) set \(\widehat{\pi}_{u r}^{[\ell+1](s+1) j}=\zeta_{u r}^{[\ell]} \widehat{\pi}_{u r}^{[\ell](s+1) j}\) such that
\[
\sum_{j=1}^{J} \widehat{\pi}_{u r}^{[\ell+1](s+1) j}=1
\]
6: end while
7: end
```

Note that logit scaling can also be seen as an ex-post adjustment of the intercept estimated in the multinomial logit model. For further details, we refer to Stephensen (2016).

### 3.2 Constrained Maximum Likelihood

The second extension was developed in this study and can be viewed as a special case of constrained maximum likelihood estimation (Dong and Wets, 2000; Chatterjee et al., 2016). Unlike logit scaling, it is a direct alignment method where the consistency to the regional benchmarks is achieved within model parameter estimation of the multinomial logit model. This is achieved by solving the constrained minimization problem

$$
\begin{equation*}
\min _{\boldsymbol{\theta}_{1}, \ldots, \boldsymbol{\theta}_{J}}\left\{-\left[\sum_{t=2}^{T} \sum_{i \in \mathcal{D}} l_{i}^{(t)}\left(\boldsymbol{\theta}_{1}, \ldots, \boldsymbol{\theta}_{J}\right)\right]\right\} \quad \text { s.t. } \quad \Delta_{r}^{(s) 1} \leq \epsilon_{r}^{1}, \ldots, \Delta_{r}^{(s) J} \leq \epsilon_{r}^{J} \tag{17}
\end{equation*}
$$

for all $\tilde{\mathcal{U}}_{r} \in \tilde{\mathcal{U}}$ individually. The solutions are obtained from a sequential quadratic programming approach (Kraft, 1994). At this point, providing a technical description of the computational details is beyond the scope of this paper. Therefore, we only briefly sketch
the method and refer to Kraft (1994) for deeper insights. Sequential quadratic programming allows for the inclusion of nonlinear constraints within a given minimization problem. In the process, each of the $R$ original constraint minimization problems in (17) is substituted by a series of constrained least squares problems. The algorithm optimizes successive secondorder approximations of the objective function with first-order affine approximations of the constraints. Starting point of the method is the minimization of the negative log-likelihood over the sample observations in $\mathcal{D}$. Let $\ell=1,2, \ldots$ denote the index of iterations required for model parameter estimation. Within every iteration and for a given $\tilde{\mathcal{U}}_{r} \in \tilde{\mathcal{U}}$, predictions $\widehat{\pi}_{u r}^{[\ell](s+1) j k}$ for all $u \in \tilde{\mathcal{U}}_{r}$ are produced simultaneously to model parameter estimation. Thereby, the predictions are based on the current model parameter estimates $\widehat{\boldsymbol{\theta}}_{1}^{[\ell]}, \ldots, \widehat{\boldsymbol{\theta}}_{J}^{[\ell]}$. For each region, the (potentially) resulting deviations $\Delta_{r}^{[\ell](s) 1}, \ldots, \Delta_{r}^{[\ell](s) J}$ are penalized by adding them from the regional Lagrangian. Define the negative log-likelihood

$$
\begin{equation*}
L\left(\boldsymbol{\theta}_{1}, \ldots, \boldsymbol{\theta}_{J}\right):=-\left[\sum_{t=2}^{T} \sum_{i \in \mathcal{D}} l_{i}^{(t)}\left(\boldsymbol{\theta}_{1}, \ldots, \boldsymbol{\theta}_{J}\right)\right] \tag{18}
\end{equation*}
$$

regional constraint functions

$$
\begin{equation*}
\mathcal{C}_{r}\left(\boldsymbol{\theta}_{1}, \ldots, \boldsymbol{\theta}_{J}\right):=-\sqrt{\left(\sum_{u \in \tilde{\mathcal{U}}_{r}} \sum_{j=1}^{J} \hat{\pi}_{u r}^{(s+1) j k}-\tau_{r}^{(t) k}\right)^{2}} \quad \forall r=1, \ldots, R, \tag{19}
\end{equation*}
$$

as well as the regional Lagrangians

$$
\begin{equation*}
\mathcal{L}_{r}\left(\boldsymbol{\theta}_{1}, \ldots, \boldsymbol{\theta}_{J}, \boldsymbol{\lambda}\right):=L\left(\boldsymbol{\theta}_{1}, \ldots, \boldsymbol{\theta}_{J}\right)-\boldsymbol{\lambda}^{\prime} \mathcal{C}_{r}\left(\boldsymbol{\theta}_{1}, \ldots, \boldsymbol{\theta}_{J}\right) \quad \forall r=1, \ldots, R \tag{20}
\end{equation*}
$$

where $\boldsymbol{\lambda}$ is the Lagrange multiplier. In a given iteration $\ell$ of the algorithm, a descent direction $\mathbf{d}^{[\ell]}$ is defined as a solution to the constrained least squares subproblem

$$
\begin{align*}
& \mathbf{d}^{[\ell]}=\underset{\mathbf{d}}{\operatorname{argmin}}\left\{L\left(\boldsymbol{\theta}_{1}^{[\ell]}, \ldots, \boldsymbol{\theta}_{J}^{[\ell]}\right)+\nabla L\left(\boldsymbol{\theta}_{1}^{[\ell]}, \ldots, \boldsymbol{\theta}_{J}^{[\ell]}\right)^{\prime} \mathbf{d}+\frac{1}{2} \mathbf{d}^{\prime} \nabla^{2} \mathcal{L}_{r}\left(\boldsymbol{\theta}_{1}^{[\ell]}, \ldots, \boldsymbol{\theta}_{J}^{[\ell]}, \boldsymbol{\lambda}^{[\ell]}\right) \mathbf{d}\right\}  \tag{21}\\
& \quad \text { s.t. } \quad \mathcal{C}_{r}\left(\boldsymbol{\theta}_{1}^{[\ell]}, \ldots, \boldsymbol{\theta}_{J}^{[\ell]}\right)+\nabla \mathcal{C}_{r}\left(\boldsymbol{\theta}_{1}^{[\ell]}, \ldots, \boldsymbol{\theta}_{J}^{[\ell]}\right)^{\prime} \mathbf{d} \geq 0,
\end{align*}
$$

which can be solved efficiently according to Kraft (1988). Afterwards, an appropriate step size is determined and a BFGS update is used to obtain new parameter estimates $\widehat{\boldsymbol{\theta}}_{1}^{[\ell+1]}, \ldots, \widehat{\boldsymbol{\theta}}_{J}^{[\ell+1]}$. The procedure is repeated until the constraints are satisfied. For more details, see Kraft (1994).

## 4 Simulation Study

### 4.1 Setup

The presented methods are tested within a Monte Carlo simulation study with $S=500$ runs. Thereby, we focus on two particular questions that are relevant in the context of transition probability estimation from survey data for dynamic microsimulations:

1. Can the methods obtain decent estimates when the survey sample is subject to coverage problems (i.e. when specific population groups are underrepresented)?
2. Can the methods recover regional transition dynamics when there are no regional identifiers for the survey observations?

Although both aspects can emerge from a lack in regional detail, we evaluate them individually. This allows for a clear separation of the potential adjustment effects in different scenarios. Further, we conduct two distinct simulations within the study: a model-based and a design-based. They are briefly sketched hereafter.

## Model-Based Setup

In the model-based simulation, the data used for estimation and evaluation is created artificially. This includes all population representations $\mathcal{U}, \tilde{\mathcal{U}}, \mathcal{D}$ described in Section 2.1. Note that for the study $\mathcal{U}=\tilde{\mathcal{U}}$ is defined. It would be redundant to create an artificial population $\mathcal{U}$ first, and then generate a synthetic replica $\tilde{\mathcal{U}}$ that is meant to be an artificial representation of $\mathcal{U}$. The advantage of the model-based approach is that the purely artificial creation allows for a controlled environment with respect to modelling and estimation. Therefore, it serves as a proof of concept in this study. The population $\mathcal{U}$ is created in each simulation run individually with a size of $N=100000$. Transition probability estimates are produced for the employment status (employed, unemployed) of any $i \in \mathcal{U}$. Thus, we choose $Y$ as binary variable rather than a polytomous one. This is, on the one hand, for illustrative purposes as adjustment effects are much easier to visualize in the binary case. On the other hand, it is due to the heavy computational burden of the simulation study. However, note that the simulation results are still meaningful with respect to the multinomial estimation techniques. It is well-known that a multinomial logit for $J$ categories can be restated as a set of $J-1$ binary logits.

Regarding $X$, every individual is associated with iid variables age (15-80), gender (male, female) and ISCED level (1-5). The functional relation between $Y$ and $X$ on the micro level is retrieved from a binary logit model on data from the German Microcensus 2013.

The values used for artificial employment probability definition can be found in Table 2 of the appendix. The employment status is added by drawing a state regarding the calculated probabilities. Subsequently, samples of $1 \%, 0.05 \%$ and $0.025 \%$ are drawn from $\mathcal{U}$ to calculate a logit model for the estimation of the employment status on the population data. In the simulation, we assume that the set of auxiliary variables and the regional population totals $\tau_{r}:=\sum_{i \in \mathcal{U}_{r}} y_{i r}$ are known as external benchmarks.

## Design-Based Setup

The design-based simulation is largely similar to the model-based setup. However, the important difference is that it is conducted on real-world observations obtained from the German Microcensus 2013. There is no synthetic data generation in the original sense. The advantage of this approach is that the methods are tested on actual data structures that occur in practice, where there are no ideal distribution characteristics. The sampled individuals of the Microcensus are taken as fixed population $\mathcal{U}$. In every simulation run, random samples of $0.1 \%, 0.05 \%$ and $0.025 \%$ are drawn and subsequently used for transition probability estimation. The inference is then analysed with respect to the fixed population rather than the hyper parameters as in the model-based study. The number of employed persons per region is again defined as a known benchmark. In order to examine the alignment to regional benchmarks, the sampling model is used to predict the employment status in each German federal state. In this case, the true employment rate of each federal states is assumed to be known.

## Scenarios and Implementation

With respect to the first aspect of missing regional detail, different sampling scenarios are implemented to mimic coverage problems in both simulation types. In practice, a coverage problem occurs when the sample proportions of essential characteristics don't fit the corresponding proportions in the regional population. Table 1 shows the different scenarios where disproportional sampling probabilities are used to differ in the observation proportions of $Y$ and $X$. The scenarios are repeated for all three sample sizes.

Scen. 18 Reduction of the drawing probability age $<50$ by $80 \%$
Table 1: Sampling scenarios

Regarding the second aspect of missing regional details, in every simulation run, a random sample is drawn from $\mathcal{U}$ via simple random sampling. The sample observations are drawn from all regions of the population with equal sampling probability (SRS). Thereby, all regional identifiers of the sample observations are deleted. Transition probability estimation is then conducted for one specific region at a time.

## Performance Measures

To evaluate the discussed methods with respect to transition probability estimation and predictive inference, we look at several performance measures. The first is the mean squared
deviation of the predicted state occurrence probabilities and the actual state occurrences,

$$
\begin{equation*}
\frac{1}{S \cdot N} \sum_{s=1}^{S} \sum_{i \in \mathcal{U}}\left(\hat{\pi}_{i}^{(s)}-y_{i}^{(s)}\right)^{2} \tag{22}
\end{equation*}
$$

where $y_{i}^{(s)}=1$ if the state has occurred in simulation run $s$, and 0 else. Since transition probability estimation is performed by minimizing the negative log-likelihood of the logit model, this measure is suitable for assessing goodness of fit with respect to the estimated parameters $\widehat{\boldsymbol{\theta}}^{(s)}$ on the population data. It is given by

$$
\begin{equation*}
-\sum_{i \in \mathcal{U}}\left(y_{i}^{(s)} \log \left[\frac{\exp \left(\left(\boldsymbol{x}_{i}^{(s)}\right)^{\prime} \widehat{\boldsymbol{\beta}}^{(s)}\right)}{1+\exp \left(\left(\boldsymbol{x}_{i}^{(s)}\right)^{\prime} \widehat{\boldsymbol{\beta}}^{(s)}\right)}\right]+\left(1-y_{i}^{(s)}\right) \log \left[\frac{1}{1+\exp \left(\left(\boldsymbol{x}_{i}^{(s)}\right)^{\prime} \widehat{\boldsymbol{\beta}}^{(s)}\right)}\right]\right), \tag{23}
\end{equation*}
$$

where $\widehat{\boldsymbol{\beta}}^{(s)}$ are obtained from the sample data in the $s$-th run of the simulation. The smaller the negative log-likelihood value, the better the estimated parameters fit the population. To further evaluate the model parameter estimates, we look at the (squared) differences

$$
\begin{equation*}
\boldsymbol{\beta}^{(s)}-\widehat{\boldsymbol{\beta}}^{(s)} \quad \text { and } \quad\left(\boldsymbol{\beta}^{(s)}-\widehat{\boldsymbol{\beta}}^{(s)}\right)^{2} \tag{24}
\end{equation*}
$$

of the parameters estimated on the sampling data in simulation run $s$ to the parameters of the population model. In the design-based framework, the population remains coefficients $\boldsymbol{\beta}_{\boldsymbol{s}}$ remain constant. Note that in the design-based setup, the population remains constant. Hence, $y_{i}^{(s)}=y_{i}$ and $\boldsymbol{x}_{i}^{(s)}=\boldsymbol{x}_{i}$ for all $i \in \mathcal{U}$, as well as $\boldsymbol{\beta}^{(s)}=\boldsymbol{\beta}$.

### 4.2 Model-Based Results

Although both aspects of missing regional detail have been studied in both simulation types, we focus hereafter on coverage problems to avoid repetitions. The recovery of regional transition dynamics is then discussed in the design-based setup. All additional results are included in the appendix. Logit scaling is referred to as $L S$ while constrained maximum likelihood is called Opt. The standard logit model without adjustments is denoted as Mod.

To evaluate the goodness of fit with respect to the parameters on the population data, we compare the negative log-likelihood values (21) in Figure 1. It can be seen that both Opt and LS are capable of improving the likelihood relative to Mod. Especially in case of smaller sample sizes, Opt consistently leads to better likelihood values. Accordingly, despite the absence of coverage problems in Scenario 1, the additional information on the

Figure 1: Scenario 1: negative log-likelihood values
benchmarks slightly improves the probability estimates. The mean value over 500 sampling runs is for $n=500(n=1000, n=250) 45.643$ (45.090, 46.888), for Mod, 45.412 (45.039, 45.611) for LS and $45.492(45.039,45.606)$ for Opt.

Figure 2: Scenario 10, 16, 18: negative log-likelihood values, $n=500$

Now, coverage problems with respect to the auxiliary variables are introduced via disproportional sampling. Here, the performance differences are more evident. We look at Scenario 10, 16, and 18. Figure 2 shows the strongest disproportionality scenarios for the variables sex, ISCED level and age. In all three scenarios, Opt leads to the smallest negative log-likelihood values on average. With less disproportional sampling, the results show
the same tendencies, although less pronounced. Further details can be found in Tables 4, 5 and 16 in the appendix. There is no systematic bias detectable for the estimates under Opt and LS, and they improve the probability estimates relative to Mod. The consideration of the standard error and impact of all parameters in Opt provides a more efficient and targeted adjustment relative to LS. The increasing standard deviation of the coefficients of the undercovered variable leads to the adjustment of this parameter having less impact on the overall log-likelihood of the model estimated on the sample. Additionally, the disproportionality causes a primarily small adjustment of a parameter to have much influence on the constraint of the population data.

Figure 3: Scenario 2-4: negative log-likelihood values, n=500

When coverage problems are with respect to the target variable, the efficiency discrepancies between adjusted and unadjusted estimates become very evident. Unlike the previously discussed disproportional sampling regarding to auxiliary variables, the underlying missing data mechanism now directly depends on the dependent variable $Y$. Without adjustment, this introduces a considerable bias to transition probability estimation. Figure 3 shows boxplots of the likelihood values based on samples with approx. $10 \%, 20 \%$ and $30 \%$ less employed persons (Scenario 2-4). These scenarios directly affect the intercept of the logit model, allowing LS to counteract the distortion quite well. Nevertheless, Opt (10\%: 45,513, $20 \%$ : $45,530,30 \% 45,479)$ displays slightly lower mean values than LS ( $10 \%: 45,521,20 \%$ : $45,569,30 \% 45,564)$. The analysis of the squared deviations of the predicted from the actual value is very similar. It can also be shown that the sum of squared errors can be reduced after using Opt and LS. Detailed results can be found in the Tables 7, 8 and 9.

Figure 4: Scenario 1 and 4: intercept estimation, $n=500$

To consider the distribution of the estimated parameters, the densities of deviations (22) are superimposed for the intercept in Figure 4. On the left density plot, the sample was drawn without restriction (Scenario 1), in the right side employed persons were underdrawn by $30 \%$ (Scenario 4). While in the case of SRS no differences can be identified, Opt is able to reliably counteract any distortion of a biased intercept in Scenario 4.

Figure 5: Scenario 10: intercept estimation, $n=500$

A slightly different picture occurs when undercoverage is with respect to auxiliary variables, as in Figure 5. On the left, we have the intercept estimation under Scenario 4, and on the right, the regression coefficient for males is depicted. We see that both methods are
unbiased in terms of intercept estimation. However, the estimation efficiency with respect to the regression coefficient is considerably increased when accounting for the regional benchmarks. The estimation density of Opt is much more concentrated around 0 compared to Mod in that case.

### 4.3 Design-Based Results

We now focus on recovering regional transition dynamics from a sample lacking regional identifiers. The probability estimates are produced for the German federal states. In the following the results for Rhineland-Palatinate, Baden-Wuerttemberg, and Bavaria are presented. The results of the remaining federal states for different sample sizes can be found in the Tables 18, 19 and 20 of the appendix. Note that unlike the previous results, no disproportional sampling is conducted. Evaluation of results is again with respect to the $\log$-likelihood values (21).

Figure 6: -Log-likelihood Model based simulation, $n=2000$

In Figure 6, we again see the improvements of LS and Opt relative to Mod. Both methods allow for considerably better goodness of fit with respect to model parameters on the regional population - despite the fact that model parameter estimation was performed on observations from all federal states. Thereby, it is not clear whether LS or Opt obtain the best results. In the model-based setup, Opt was slightly more efficient and generally had a smaller probability of producing estimation outliers (Figure 2). However, in practice, this tendency is not observable anymore. Regarding the design-based results of the undercoverage scenarios of Table 1, see the appendix. The results are essentially identical to the
model-based setup. Therefore, we omitted a dedicated interpretation at this point.

## 5 Discussion

The estimation of regional transition probabilities from survey data lacking in regional detail has been investigated. Missing regional observations can either lead to coverage problems in local samples or prevent a spatial localization of the sample observations. It could be shown that common estimation methods obtain inefficient or even biased results in these cases. We discussed two methods that are able to account for regional heterogeneity by aligning micro level transition probability estimates to regional benchmarks. Both methods allowed for considerably more efficient estimates in all scenarios. In the light of the coverage problems, the most significant efficiency gains were realized when undercoverage was with respect to the variable transition probability estimates were required for. Regarding the missing regional identifiers, both adjustments were able to recover the transition dynamics more efficiently relative to standard methods.

The findings of this study have major implications for future research conducted by means of dynamic microsimulations. The basic principle of this simulation type is the projection of system units into future periods with micro-level transition probabilities. If these probabilities don't accurately represent regional transition dynamics of the real world, the obtained simulation results are not reliable. In general, both logit scaling and constrained maximum likelihood are suitable to solve this problem. However, from a practical perspective, the researcher may want to choose one of them. One that note, Stephensen (2016) pointed out several criteria that determine a good alignment method in the context of dynamic microsimulations. The subsequent discussion is partially guided by these aspects.

Both techniques adjust the probability estimates such that they are consistent with the regional benchmarks. Thereby, both allow for multinomial alignment in a logit environment, are formulated symmetrically, and retain zero probabilities in the process. A difference is that logit scaling retains the original shape of the probability distribution. In constrained maximum likelihood, this is not the case due to the adjustment of multiple parameters simultaneously. However, our point of view is that depending on the context, it may not be desirable to retain the original shape of the distribution. The simulation study showed that in the case of an undercoverage regarding the target variable, the model parameter estimates are considerably biased. Subsequently, the resulting probability distribution gets distorted and may misrepresent real-world transition dynamics. Another point is the easy and efficient implementation of the methods in the simulation process. In general, the
algorithm used for logit scaling is certainly easier and faster to apply than the sequential quadratic programming approach we propose. But it should be recalled that logit scaling is an ex-post alignment method. Thus, it has to be performed for each period of the simulation horizon individually. The constrained maximum likelihood approach allows for direct alignment in the process of model parameter estimation. Accordingly, it has to be performed only once in the initial phase of the simulation. Further, there are many software packages in which sequential quadratic programming is implemented such that they can be easily applied. Further research should be conducted on the behaviour of adjustment methods when regional benchmarks are not known, but also estimated from survey data. This setting is more likely in the light of public reporting and data sources of official statistics. In principal, the box constraints discussed for the regional benchmarks can be constructed to account for estimation errors, for example in terms of confidence intervals. However, this might not be the optimal choice since the optimization algorithms for alignment will stop when the estimates are consistent with the interval boundaries. Since regional estimates of population characteristics are often subject to high uncertainty due to a lack in regional detail as well, boxes may be very large and the efficiency gains from adjustment decrease.

## Acknowledgements

This study was conducted within the research project Regionale Mikrosimulationen und Indikatorensysteme (REMIKIS) funded the Nikolaus Koch Foundation, as well as the research group Sektorenübergreifendes kleinräumiges Mikrosimulationsmodell (MikroSim) funded by the German Research Foundation. We kindly thank all involved parties for the financial support.
