# Poisson representation of a Ewens fragmentation process * 

Alexander Gnedin ${ }^{\dagger}$ and Jim Pitman ${ }^{\ddagger}$

July 24, 2018

#### Abstract

A simple explicit construction is provided of a partition-valued fragmentation process whose distribution on partitions of $[n]=\{1, \ldots, n\}$ at time $\theta \geq 0$ is governed by the Ewens sampling formula with parameter $\theta$. These partition-valued processes are exchangeable and consistent, as $n$ varies. They can be derived by uniform sampling from a corresponding mass fragmentation process defined by cutting a unit interval at the points of a Poisson process with intensity $\theta x^{-1} \mathrm{~d} x$ on $\mathbb{R}_{+}$, arranged to be intensifying as $\theta$ increases.

## 1 Introduction

There has been much recent interest in models for random processes of fragmentation and coagulation: see Chapter 5 of [13] and the recent book [3]. Mekjian and others [4, 10, 11, 12] have considered Ewens partitions with parameter $\theta$ as a model for fragmentation phenomena, with the intuitive notion that increasing $\theta$ corresponds to further fragmentation. But it does not seem obvious how to construct a nice Markovian fragmentation process corresponding to this idea.

It was pointed out in [13] that it is possible to construct a sequence of partition-valued processes $\left(\Pi_{n, \theta}, \theta \geq 0\right)(n=1,2, \ldots)$ with the following properties:

- (Ewens distribution) $\Pi_{n, \theta}$ is for each $n=1,2, \ldots$ and $\theta \geq 0$ a random partition of the set $[n]:=\{1,2, \ldots, n\}$, with distribution determined by the following formula:

[^0]for each composition $\left(n_{1}, \ldots, n_{k}\right)$ of $n=\sum_{i=1}^{k} n_{i}$, and each partition $\pi$ of $[n]$ into $k$ blocks of sizes $n_{1}, \ldots, n_{k}$,
\[

$$
\begin{equation*}
\mathbb{P}\left(\Pi_{n, \theta}=\pi\right)=\frac{\theta^{k-1}}{[\theta+1]_{n-1}} \prod_{i=1}^{k}\left(n_{i}-1\right)! \tag{1}
\end{equation*}
$$

\]

where $[x]_{m}:=x(x+1) \cdots(x+m-1)$ is the Pochhammer factorial;

- (fragmentation) $\Pi_{n, \theta}$ is a refinement of $\Pi_{n, \phi}$ if $\theta>\phi$, for all $n \geq 1$, that is each block of $\Pi_{n, \phi}$ is some union of blocks of $\Pi_{n, \theta}$;
- (consistency) for each $n<m$ a process with the same distribution as $\left(\Pi_{n, \theta}, \theta \geq 0\right)$ is obtained by restriction of $\left(\Pi_{m, \theta}, \theta \geq 0\right)$ to $[n]$;
- (exchangeability) for each $n$ the law of $\left(\Pi_{n, \theta}, \theta \geq 0\right)$ is invariant under permutations of the set $[n]$.

We call a sequence of partition-valued processes $\left(\Pi_{n, \theta}, \theta \geq 0\right)(n=1,2, \ldots)$ with these properties a family of Ewens fragmentations. One family of Ewens fragmentations associated with Kingman's coalescent was analysed in [2].

Some general theory [5 implies that any such family of processes can be defined in the strong sense consistently (i.e. so that $\left.\Pi_{m, \theta}\right|_{[n]}=\Pi_{n, \theta}$ for $m>n$ ) on a single probability space by means of uniform sampling of points engaged in a process of fragmentation of a total mass 1 into a countable collection of submasses with sum 1, with more and more refined splitting of the submasses as the time parameter $\theta$ increases. See [3, Chapter 3] and [13, Chapter 5] for further background and references.

The problem was posed in [13] of characterising the dynamics of a family of Ewens fragmentations, preferably in a Markovian way. For applications, it is desirable to have a model which can easily be simulated for modest values of $n$. But previous efforts fall short in this respect. In this note we partly solve this problem by constructing a new family of Ewens fragmentations. Our family is not Markovian, but it enjoys the Markov property and follows a very simple transition rule when viewed as a fragmentation process in the extended space of ordered partitions. This simplification by passing to an ordered structure extends our previous work on regenerative partitions and their relatives [7, 8, (9).

## 2 Construction

Recall that a composition of $n$ is a sequence of positive integers $\left(n_{1}, \ldots, n_{k}\right)$ with sum $n$. We regard a composition of $n$ as a way of distributing $n$ unlabelled balls in an ordered sequence of $k$ non-empty boxes, with $n_{i}$ balls in the $i$ th box. A composition of $n$ is also conveniently encoded by the binary sequence of 0 's and 1 's obtained by concatenating subsequences of the form $1,10,100, \ldots$, where the $i$ th subsequence in the concatenation has length $n_{i}$. So the symbols 1 occur at places $1, n_{1}+1, n_{1}+n_{2}+1, \ldots \sum_{i=1}^{k-1} n_{i}+1$. Using a particular composition $(3,4,1)$ of 8 for illustration, the balls-in-boxes picture is suggested by the notation $[000][0000][0]$. The binary representation is obtained by replacing each [0 by a 1 and deleting each ] to obtain the sequence 10010001. Let $x$ and $y$
be two compositions of $n$, each represented as a binary sequence, say $x=\left(x_{i}, 1 \leq i \leq n\right)$ and $y=\left(y_{i}, 1 \leq i \leq n\right)$. Say $x$ is a refinement of $y$ if $x_{i} \geq y_{i}$ for every $i$. In terms of the balls-in-boxes picture, $x$ is derived from $y$ by splitting boxes into sub-boxes, and in terms of the binary representation $x$ is derived by switching some 0 's to 1 's. For instance, 11010101 is a refinement of 10010001 .

Given a stochastic process $\left(C_{n, \theta}, \theta \geq 0\right)$, with values in compositions of $n$ we define an associated partition-valued process $\left(\Pi_{n, \theta}, \theta \geq 0\right)$ by first assigning each of the $n$ places for a ball in the balls-in-boxes representation a number in $[n]$ according to a uniform random permutation of $[n]$ independent of $\left(C_{n, \theta}, \theta \geq 0\right)$, thus obtaining an ordered partition of $[n]$, then ignoring the order of the boxes to obtain a partition of $[n]$. If $\left(C_{n, \theta}, \theta \geq 0\right)$ is refining as $\theta$ increases then the associated partition-valued process $\left(\Pi_{n, \theta}, \theta \geq 0\right)$ is a fragmentation process whose law is invariant under permutations of $[n]$. The process $\left(\Pi_{n, \theta}, \theta \geq 0\right)$ then describes a process of randomly splitting up a collection of balls labelled by $[n]$ into an unordered collection of boxes.

Theorem 1. Let $\Theta_{j}$ for $j=1,2, \ldots$ be a sequence of independent random variables with distributions

$$
\begin{equation*}
\mathbb{P}\left(\Theta_{j} \leq \theta\right)=\theta /(\theta+j-1), \quad \theta \geq 0 \tag{2}
\end{equation*}
$$

(where $0 / 0=1$ ). Let $C_{n, \theta}$ for $n=1,2, \ldots$ be the random composition of $n$ whose binary representation is the sequence of indicator variables $1\left(\Theta_{j} \leq \theta\right)$ for $1 \leq j \leq n$. Then the sequence $\left(\Pi_{n, \theta}, \theta \geq 0\right)$ of partition-valued process associated with $\left(C_{n, \theta}, \theta \geq 0\right)$ defines a family of Ewens fragmentations.

That $\Pi_{n, \theta}$ has the Ewens distribution (11) can be read from the known result [1, 9, 13] that in the binary representation of the composition of $n$ derived from the block sizes of a Ewens partition of $[n]$ in reversed size-biased order, the digits are independent Bernoulli variables with parameters $\theta /(\theta+j-1)$ as in (22). The device (2) with independent variables $\Theta_{j}$ is then the simplest way to make these indicators simultaneously for all $j$ and $n$ to be increasing in $\theta$, which is all that is needed to make ( $\Pi_{n, \theta}, \theta \geq 0$ ) a Ewens fragmentation. What is much less obvious is the consistency of these processes for various $n$. To put this another way, if in the process of splitting a set of $m$ balls according to the indicators $1\left(\Theta_{j} \leq \theta\right)$ for $1 \leq j \leq m$ we pass to the balls-in-boxes picture and just observe the splitting process restricted to a uniformly chosen random subset of $n<m$ balls, this subprocess is identical in distribution to the process of splitting of the first $n$ balls using the indicators $1\left(\Theta_{j} \leq \theta\right)$ for $1 \leq j \leq n$. This sampling consistency property of compositions, which is so intuitive in the balls-in-boxes picture, is quite painful to express entirely in the binary encoding. We circumvent that difficulty by deriving consistency from the Poisson representation of the corresponding mass fragmentation model, which is introduced in the next section. See also [9] for a more extensive discussion of such consistency properties of partition structures derived by random sampling from self-similar random sets, like the self-similar Poisson process in the next section or the zero set of a Brownian motion.

## 3 Poisson representation of the mass fragmentation

Let $\left(T_{i}, V_{i}\right)$ be a listing of the points of a homogeneous Poisson point process on the positive quadrant $\mathbb{R}_{+}^{2}$ with rate 1 per unit area. For each fixed $\theta>0$, the random countable set

$$
Z_{\theta}:=\left\{T_{i}: 0<T_{i}<1 \text { and } V_{i} \leq \theta / T_{i}\right\}
$$

is then the set of points of a Poisson process on $[0,1]$ with intensity $\theta t^{-1} \mathrm{~d} t$. To orient the reader, we start by recalling some well known properties of $Z_{\theta}$ and the induced random composition [1, 9, 6, 13].
(i) Let $Y_{1, \theta}>Y_{2, \theta}>\cdots$ be the points of $Z_{\theta}$ in decreasing order. Then

$$
Y_{j, \theta}=\prod_{i=1}^{j} W_{i, \theta}
$$

where the $W_{i, \theta}(i=1,2, \ldots)$ are independent and identically distributed random variables with $\operatorname{beta}(\theta, 1)$ distribution.
(ii) If $P_{j, \theta}$ is the length of the $j$ th component interval of $[0,1] \backslash Z_{\theta}$, working from right to left, that is $P_{j, \theta}=Y_{j-1, \theta}-Y_{j, \theta}$ where $Y_{0, \theta}:=1$, then

$$
P_{j, \theta}=\left(1-W_{j, \theta}\right) \prod_{1=1}^{j-1} W_{i, \theta}
$$

for $W_{i, \theta}$ i.i.d. $\operatorname{beta}(\theta, 1)$ as before. The distribution of this random discrete probability distribution $\left(P_{j, \theta}, j \geq 1\right)$ is known as the $\operatorname{GEM}(\theta)$ distribution.
(iii) The distribution of the decreasing rearrangement of $\left(P_{j, \theta}, j \geq 1\right)$ is the PoissonDirichlet distribution with parameter $\theta$.
(iv) Let $U_{1}, U_{2}, \ldots$, be a sequence of independent uniform $[0,1]$ variables, independent of $Z_{\theta}$, and define a random partition $\Pi_{\infty, \theta}$ of the set $\mathbb{N}$ of positive integers to be the collection of equivalence classes for the random equivalence relation: $i \sim^{\theta} j$ if and only if either $i=j$ or both $U_{i}$ and $U_{j}$ fall in the same component interval of $[0,1] \backslash Z_{\theta}$. Then $\Pi_{\infty, \theta}$ is an exchangeable random partition of the infinite set $\mathbb{N}$, whose restriction $\Pi_{n, \theta}$ to $[n]$ is a Ewens partition governed by (11) for each $n$.
(v) Let $U_{n, j}$ be the $j$ th smallest value among $U_{1}, \ldots, U_{n}$, and let $X_{n, j}(\theta)$ be the indicator of the event that $U_{n, j}$ is the least value among those of the $n$ values which fall in some component interval of $[0,1] \backslash Z_{\theta}$. Then for each fixed $n$ and $\theta$, the $X_{n, j}(\theta)$ for $j=1,2, \ldots, n$ are independent, with

$$
\begin{equation*}
\mathbb{P}\left(X_{n, j}(\theta)=1\right)=\theta /(\theta+j-1) \tag{3}
\end{equation*}
$$

More precisely, the sequence $\left(X_{n, j}(\theta), 1 \leq j \leq n\right)$ is the binary encoding of a random composition $C_{n, \theta}$ of $n$ which is a particular ordering of the sizes of blocks of $\Pi_{n, \theta}$. If
the blocks of $\Pi_{n, \theta}$ are, say, $B_{1}, \ldots, B_{k}$, then the sizes of these blocks appear in the composition in increasing order of values of $\min _{i \in B_{k}} U_{i}{ }^{1}$.

An immediate consequence of the above construction of $Z_{\theta}$ from a Poisson process in the positive quadrant is that the random set $Z_{\theta}$ increases as $\theta$ increases. Consequently, the various quantities introduced above describe a process of fragmentation of $[0,1]$ into subintervals. In particular, the partition valued process $\left(\Pi_{n, \theta}, \theta \geq 0\right)$ is refining as $\theta$ increases, and each of the processes $\left(X_{n, j}(\theta), \theta \geq 0\right)$ is increasing as $\theta$ increases. Consistency and exchangeability of the processes $\left(\Pi_{n, \theta}, \theta \geq 0\right)$ are obvious from (iv).

The proof of the consistency property claimed in Theorem $\dagger$ is completed by the following lemma, which shows that in this Poisson setup the indicator variables $\left(X_{n, j}(\theta), 1 \leq j \leq\right.$ $n$ ) in the binary expansion of the composition $C_{n, \theta}$ associated with the natural ordering of blocks of $\Pi_{n, \theta}$ (as in (v)) can be derived from independent variables ( $\Theta_{n, j}, 1 \leq j \leq n$ ) with the same distribution as $\left(\Theta_{j}, 1 \leq j \leq n\right)$ in Theorem

Lemma 2. Let $\Theta_{n, j}:=\inf \left\{\theta: X_{n, j}(\theta)=1\right\}$, so that $X_{n, j}(\theta)$ may be represented as

$$
X_{n, j}(\theta)=1\left(\Theta_{n, j} \leq \theta\right)
$$

Then for each fixed $n$ the $\Theta_{n, j}$ are independent random variables with

$$
\mathbb{P}\left(X_{n, j}(\theta)=1\right)=\mathbb{P}\left(\Theta_{n, j} \leq \theta\right)=\theta /(\theta+j-1), \quad(j=1, \ldots, n)
$$

Proof. Fix $\theta_{j}>0$ for $j=2, \ldots, n$. Observe that the event $\left(\Theta_{n, j}>\theta_{j}\right)$ occurs if and only if there is no point $\left(T_{i}, V_{i}\right)$ of the Poisson process with $T_{i} \in\left[U_{n, j-1}, U_{n, j}\right]$ and $V_{i} \leq \theta / T_{i}$. Therefore

$$
\mathbb{P}\left(\cap_{j=2}^{n}\left(\Theta_{n, j}>\theta_{j}\right) \mid U_{n, j}, 1 \leq j \leq n\right)=\exp \left(-\sum_{j=2}^{n} \int_{U_{n, j-1}}^{U_{n, j}} \frac{\theta_{j}}{t} \mathrm{~d} t\right)=\prod_{j=2}^{n}\left(\frac{U_{n, j-1}}{U_{n, j}}\right)^{\theta_{j}}
$$

and hence

$$
\mathbb{P}\left(\cap_{j=2}^{n}\left(\Theta_{n, j}>\theta_{j}\right)=\mathbb{E}\left[\prod_{j=2}^{n}\left(\frac{U_{n, j-1}}{U_{n, j}}\right)^{\theta_{j}}\right]=\prod_{j=2}^{n} \frac{j-1}{j-1+\theta_{j}},\right.
$$

because the ratios $U_{n, j-1} / U_{n, j}$ are independent with beta $(j-1,1)$ distributions, $2 \leq j \leq n$.

As before, let $\left(C_{n, \theta}, \theta \geq 0\right)$ be the process of refining compositions of $n$, defined either through indicators as in Theorem or by means of the Poisson construction as in (v) above. Immediately from the definition, we have:

Corollary 3. $\left(C_{n, \theta}, \theta \geq 0\right)$ is a Markov process whose inhomogeneous transition rates are determined by the rule: if at time $\theta$ the state is the composition of $n$ encoded by some binary sequence starting with 1 , each 0 is switching to 1 at rate $1 /(\theta+j-1)$, where $j$ is the place of this 0 in the sequence, while all other transition rates are trivial.

[^1]Proof. Indeed,

$$
\mathbb{P}\left(\Theta_{j} \in[\theta, \theta+\mathrm{d} \theta] \mid \Theta_{j}>\theta\right)=\frac{\left(\frac{\theta}{\theta+j-1}\right)^{\prime} \mathrm{d} \theta}{1-\frac{\theta}{\theta+j-1}}=\frac{\mathrm{d} \theta}{\theta+j-1}
$$

If we view $\Pi_{\infty, \theta}$ together with the total ordering of the blocks, as induced by the natural order of intervals (recall (iv)), we obtain an exchangeable ordered partition $\Pi_{\infty, \theta}^{*}$ of $\mathbb{N}$. Let $\Pi_{n, \theta}^{*}$ be its restriction to $[n]$. The law of $\Pi_{n, \theta}^{*}$ is given by the ordered version of the Ewens sampling formula (1):

$$
\mathbb{P}\left(\Pi_{n, \theta}^{*}=\pi^{*}\right)=\frac{\theta^{k-1}}{[\theta+1]_{n-1}} \prod_{j=1}^{k} \frac{n_{j}!}{n_{1}+\cdots+n_{j}}
$$

for every $\pi^{*}$ ordered partition of $[n]$ with block sizes $\left(n_{1}, \ldots, n_{k}\right)$. The process $\left(\Pi_{n, \theta}, \theta \geq\right.$ $0)$ is Markovian for every $n$. The transition mechanism of $\left(\Pi_{n, \theta}^{*}, \theta \geq 0\right)$ is determined by that of ( $C_{n, \theta}, \theta \geq 0$ ) and the following allocation rule ${ }^{2}$ : each time a block $B_{j}$ of size $a$ splits in two fragments of sizes $\xi$ and $\eta$, all $\binom{a}{\xi}$ possible allocations of the elements of $B_{j}$ among the offspring fragments are equally likely.

## 4 Further properties

In principle, the finite dimensional distributions of $\left(\Pi_{n, \theta}, \theta \geq 0\right)$ may be determined by some summations of probabilities determined by the Markov process ( $\left.C_{n, \theta}, \theta \geq 0\right)$. But such formulas appear to be of limited value. It appears that the process $\left(\Pi_{n, \theta}, \theta \geq 0\right)$ is not Markovian.

Proof that for $n>2$ the fragmentation process is not Markovian Consider the random time $\widehat{\Theta}_{n}$ of the first split, that is

$$
\widehat{\Theta}_{n}=\min _{2 \leq j \leq n} \Theta_{n, j}=\inf \left\{\theta: \Pi_{n, \theta} \neq\{[n]\}\right\},
$$

where $\Pi_{n, 0}=\{[n]\}$ is the initial partition with a single block. To show that the Markov property of the fragmentation process $\left(\Pi_{n, \theta}, \theta \geq 0\right)$ does not hold for every $n>2$ we shall focus on the conditional probability

$$
Q(t):=\mathbb{P}\left(\Pi_{n, \theta}=\lambda \mid \Pi_{n, \phi}=\lambda, \Pi_{n, t}=\lambda\right)=\mathbb{P}\left(\Pi_{n, \theta}=\lambda \mid \Pi_{n, \phi}=\lambda, \widehat{\Theta}_{n}<t\right)
$$

where $\phi, \theta$ are considered as parameters, $0<t<\phi<\theta$, and $\lambda$ is the partition of $[n]$ in two blocks $\{1\}$ and $\{2, \ldots, n\}$. To disprove the Markov property it is sufficient to show that $Q(t)$ is not constant as $t$ varies.

Note that $\Pi_{n, \phi}=\lambda$ is only possible when the composition $C_{n, \phi}$ assumes either the value $1100 \ldots 0$ or the value $100 \ldots 01$, and conditionally given either of these values $\Pi_{n, \phi}$

[^2]equals $\lambda$ with probability $1 / n$ (as a consequence of exchangeability). Working out this dichotomy,
\[

$$
\begin{aligned}
& \mathbb{P}\left(\Pi_{n, \phi}=\lambda, \widehat{\Theta}_{n}<t\right)= \\
& \mathbb{P}\left(\Theta_{n, 2}<t, \Theta_{n, n}>\phi ; \Theta_{n, 3}>\phi, \ldots, \Theta_{n, n-1}>\phi\right) \frac{1}{n}+ \\
& \mathbb{P}\left(\Theta_{n, 2}>\phi, \Theta_{n, n}<t ; \Theta_{n, 3}>\phi, \ldots, \Theta_{n, n-1}>\phi\right) \frac{1}{n}= \\
& \frac{t}{t+2-1}\left(1-\frac{\phi}{\phi+n-1}\right) P(\phi) \frac{1}{n}+\left(1-\frac{\phi}{\phi+2-1}\right) \frac{t}{t+n-1} P(\phi) \frac{1}{n}= \\
& \left(\frac{t(n-1)}{(t+1)(\phi+n-1)}+\frac{t}{(\phi+1)(t+n-1)}\right) P(\phi) \frac{1}{n}
\end{aligned}
$$
\]

where for shorthand $P(\phi):=\mathbb{P}\left(\Theta_{n, 3}>\phi, \ldots, \Theta_{n, n-1}>\phi\right)$. Noting the inclusion

$$
\left\{\Pi_{n, \theta}=\lambda, \widehat{\Theta}_{n}<t\right\} \subset\left\{\Pi_{n, \phi}=\lambda, \widehat{\Theta}_{n}<t\right\}
$$

and applying the above formula to the event on the left-hand side, we compute

$$
Q(t)=\frac{\mathbb{P}\left(\Pi_{n, \theta}=\lambda, \widehat{\Theta}_{n}<t\right)}{\mathbb{P}\left(\Pi_{n, \phi}=\lambda, \widehat{\Theta}_{n}<t\right)}=\left(\frac{t(n \theta+2 n-2)+(n-1)^{2}(\theta+1)+\theta+n-1}{t(n \phi+2 n-2)+(n-1)^{2}(\phi+1)+\phi+n-1}\right) \frac{P(\phi)}{P(\theta)}
$$

This does not depend on $t$ if and only if

$$
\frac{n \theta+2 n-2}{n \phi+2 n-2}=\frac{(n-1)^{2}(\theta+1)+\theta+n-1}{(n-1)^{2}(\phi+1)+\phi+n-1},
$$

or, equivalently, if and only if the polynomial

$$
\begin{gathered}
(n \theta+2 n-2)\left((n-1)^{2}(\phi+1)+\phi+n-1\right)= \\
n\left(n^{2}-2 n+2\right) \theta \phi+n^{2}(n-1) \theta+2(n-1)\left(n^{2}-2 n+2\right) \phi+2 n(n-1)^{2}
\end{gathered}
$$

is symmetric in $\phi$ and $\theta$. To maintain symmetry we must have

$$
n^{2}(n-1)=2(n-1)\left(n^{2}-2 n+2\right)
$$

which forces positive $n$ to be either 1 or 2 . Thus for $n>2$ the partition-valued process is not Markovian (while it is trivially Markovian for $n=1$ or 2 ).

Transition rates of the Ewens fragmentation Given the value $\pi$ of $\Pi_{n, \theta}$, the composition $C_{n, \theta}$ can be recovered by arranging the sequence of block sizes of $\pi$ in the reversed size-biased order. This property taken together with Corollary 3 allows to compute the transition rates. To illustrate the method, suppose that at time $\theta$ the partition $\Pi_{n, \theta}$ is in state $\pi$ with block sizes $\{a, b\}$, and let $\sigma$ be some nontrivial refinement of $\pi$ with block
sizes $\{\xi, \eta, b\}$, so $\xi+\eta=a$. Suppose first that $a \neq b, \xi \neq \eta$. Then $C_{n, \theta}=(a, b)$ with probability $b /(a+b)$, and $C_{n, \theta}=(b, a)$ with probability $a /(a+b)$. Inspecting all possibilities we see that the fragmentation process jumps from $\pi$ to $\sigma$ at rate

$$
\frac{b}{a+b}\left(\frac{1}{\theta+\xi}+\frac{1}{\theta+\eta}\right)\binom{a}{\xi}^{-1}+\frac{a}{a+b}\left(\frac{1}{\theta+\xi+b}+\frac{1}{\theta+\eta+b}\right)\binom{a}{\xi}^{-1}
$$

where the binomial coefficients accounts for the number of ways of allocating the elements of the splitting block among two new fragments. A minute thought shows that the formula is still valid in the case $a=b$; but if $\xi=\eta$ the above expression should be halved.

In principle, there exists a Markovian family of Ewens fragmentations, with the same transition rates as that of $\left(\Pi_{n, \theta}\right)$ 's. However, this seems to be of little use, because the formulas for these rates become increasingly complicated when the number of blocks grows.

Comparison with the Ewens fragmentation derived from Kingman's coalescent Another family of Ewens fragmentations was derived in [2] from Kingman's coalescent tree. These fragmentations are not Markovian in the proper sense, and no extended Markov property for them is known. We show next that the partition-valued process in [2] is different from the process constructed in this paper.

As before, consider the time of the first split $\dot{\widehat{\Theta}}_{n}$. Let $I_{n}+1$ be the almost surely unique index $j$ which makes $\widehat{\Theta}_{n}=\Theta_{n, j}$. Then the split at time $\widehat{\Theta}_{n}$ creates a partition $\Pi_{n, \widehat{\Theta}_{n}}$ with two blocks of sizes $I_{n}$ and $n-I_{n}$. Conditioning on $\widehat{\Theta}_{n}$ gives

$$
\begin{equation*}
\mathbb{P}\left(I_{n}=i\right)=\int_{0}^{\infty} \frac{\mathbb{P}\left(\Theta_{n, i+1} \in \mathrm{~d} \theta\right)}{\mathbb{P}\left(\Theta_{n, i+1}>\theta\right)} \prod_{2 \leq j \leq n} \mathbb{P}\left(\Theta_{n, j}>\theta\right) \tag{4}
\end{equation*}
$$

which simplifies to

$$
\begin{equation*}
\mathbb{P}\left(I_{n}=i\right)=(n-1)!\int_{0}^{\infty} \frac{\mathrm{d} \theta}{(\theta+i)[\theta+1]_{n-1}} . \tag{5}
\end{equation*}
$$

In particular, for $n=4$ this gives

$$
\begin{array}{r}
\mathbb{P}\left(I_{4}=1\right)=6\left(-\log 2+\frac{1}{4} \log 3+\frac{1}{2}\right) \\
\mathbb{P}\left(I_{4}=2\right)=6\left(\frac{1}{2} \log 3-\frac{1}{2}\right) \\
\mathbb{P}\left(I_{4}=3\right)=6\left(\log 2-\frac{3}{4} \log 3-\frac{1}{6}\right) .
\end{array}
$$

Compare the second of these evaluations with the corresponding formula in [2, Section 7.1] to see that this Ewens fragmentation process evolves differently to the Ewens fragmentation derived from Kingman's coalescent, which has a different distribution on partitions of [4] with two blocks at the time of the first split. Neither of these distributions is that of $\Pi_{4, \theta}$ given that this partition has exactly two blocks, even though this conditional
distribution does not depend on $\theta$. This common conditional distribution is the Gibbs distribution on partitions of [4] into 2 blocks which assigns probability proportional to $\left(n_{1}-1\right)!\left(n_{2}-1\right)$ ! to each partition of [4] into two blocks of sizes $n_{1}$ and $n_{2}$.

It is still an open question for which $n$ there exists a discrete time fragmentation process on partitions of $[n]$ whose distribution at time $k$ is the distribution on partitions of $[n]$ into $k$ blocks which assigns each such partition into blocks of sizes $\left\{n_{1}, \ldots, n_{k}\right\}$ a probability proportional to $\prod_{i=1}^{k}\left(n_{i}-1\right)$ !.

[^1]:    ${ }^{1}$ Strictly speaking, this defines $C_{n, \theta}$ in terms of $U_{j}$ 's and $Z_{\theta}$, rather than through $\Pi_{n, \theta}$. Conditionally given $\Pi_{n, \theta}=\left\{B_{1}, \ldots, B_{k}\right\}$ the composition has the same distribution as the sequence $\# B_{j}$ arranged by decrease of minimal elements min $B_{j}$. Conditionally given the induced partition $\left\{\# B_{j}, j \leq k\right\}$ of integer $n$, this arrangement is the inverse size-biased ordering of the block sizes.

[^2]:    ${ }^{2}$ Which is common for all exchangeable fragmentation processes.
