This paper completes the construction of the Brauer tree of the sporadic simple Thompson group in characteristic 19. Our main computational tool to arrive at this result is a new parallel implementation of the DirectCondense method.

## 1. INTRODUCTION AND RESULTS

Let Th be the sporadic simple Thompson group. In [Hiss and Lux 1989] the Brauer tree of the principal 19-block of Th has been determined up to two possibilities. In this note, we show which of them is the correct one, and we describe the new computational techniques that enabled us to decide between these two possibilities. We believe that the methods presented here will be powerful enough to solve even more difficult problems in the modular character theory of the sporadic groups.

As a general reference for the theory of blocks of cyclic defect, the interpretation of a Brauer tree and its planar embedding, see the introduction of [Hiss and Lux 1989]. The planar embedded Brauer tree of the principal 19-block of Th is given in Figure 1; it also appears in [Hiss and Lux 1989, p. 277 , Case I]. Its nodes are labelled by the numbers of the corresponding ordinary irreducible characters, where we use the notation for the ordinary irreducible characters of Th as they are given in [Conway et al. 1985, p. 176] and in the GAP software [Schönert et al. 1994]. In Table 1 we list the ordinary irreducible characters of $G$ lying in the principal 19-block, plus some additional information concerning them.

The degrees of the irreducible Brauer characters are given in Table 2. A Brauer character that

| $\chi$ | Degree | CC | 19A | $\chi$ | Degree | CC | 19A |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: |
| 1 | 1 | r | 1 | 23 | 4096000 | 22 | -1 |
| 2 | 248 | r | 1 | 25 | 4881384 | r | -1 |
| 4 | 27000 | r | 1 | 26 | 4936750 | r | -1 |
| 5 | 27000 | 4 | 1 | 29 | 6696000 | 30 | 1 |

TABLE 1. Ordinary irreducible characters lying in the principal 19-block of Th. The column headed "CC" contains the entry "r" in rows corresponding to real-valued characters; otherwise it contains the number of the complex conjugate character. The last column contains the values of the characters on elements of class 19A. Characters that are connected on the Brauer tree must have unequal values on this class.

FIGURE 1. The Brauer Tree mod 19 of the sporadic simple Thompson group Th.
corresponds to an edge of the tree connecting $\chi_{i}$ and $\chi_{j}$, with $i<j$, is denoted by $\varphi_{i}$.

To obtain the result of this paper, we had to apply a new condensation technique to a module of dimension 976841775 , the permutation module on the cosets of the third maximal subgroup of Th. The condensed module has dimension 1403 over $\mathbb{F}_{19}$ and can be analyzed with the MeatAxe [Parker 1984], giving the result. We have used the MeatAxe implementation in C by Michael Ringe [1994]. The details are given in Section 2. We remark that in order to arrive at only two possibilities for the Brauer tree in [Hiss and Lux 1989], we

| Char. | Degree |  |  | Char. |  | Degree |
| :--- | ---: | :--- | ---: | :---: | :---: | :---: |
|  |  |  |  | $\varphi_{23}$ |  |  |
| $\varphi_{1}$ | 248 |  | 4096000 |  |  |  |
| $\varphi_{2}$ | 27000 |  | $\varphi_{25}$ | 4881383 |  |  |
| $\varphi_{4}$ | 27000 |  | $\varphi_{29}$ | 4936502 |  |  |
| $\varphi_{5}$ | 85995 |  | $\varphi_{30}$ | 696000 |  |  |
| $\varphi_{9}$ | 85995 |  | $\varphi_{35}$ | 16490123 |  |  |
| $\varphi_{10}$ | 740637 |  | $\varphi_{36}$ | 16490123 |  |  |
| $\varphi_{12}$ | 740637 |  | $\varphi_{43}$ | 71335123 |  |  |

| $\varphi_{22}$ |  |  |  |  |  |  |

TABLE 2. Degrees of the irreducible Brauer characters.
had to rule out several other possibilities using sophisticated techniques involving Green correspondence. We have checked the results of the condensation against these other possible trees. None of them is consistent with the condensation results.

The condensation method was originally conceived by Parker and Thackray [Thackray 1981], and is also described in [Ryba 1990] and [Lux et al. 1994]. The idea of the new DirectCondense technique goes back to Parker and Wilson, and a fuller discussion is given in [Cooperman and Tselman 1996]. In Section 3 we give details on the implementation and special techniques for doing the condensation in practice.

## 2. CONDENSATION

### 2.1. General Remarks

Let $A$ be a finite-dimensional algebra over the field $F$ and $e \in A$ be an idempotent. Let $\bmod -A$ denote the category of finitely generated right $A$-modules. Then the exact functor

$$
? \otimes_{A} A e: \bmod -A \longrightarrow \bmod -e A e: M \longmapsto M e
$$

is called the condensation functor with respect to $e$, and $M e$ is called the condensation of $M$. Condensation gives us a tool to analyse the submodule structure of $M$ by looking at $M e$ instead. We will apply this for $F$ a field of prime characteristic $p$, $A=F G$, where $G$ is a finite group, $K$ the condensation subgroup of $G$ having order $|K|$ prime to $p$, and

$$
e=e_{K}=|K|^{-1} \cdot \sum_{g \in K} g \in F G
$$

If $M$ is an $F G$-module, then $M e$ is the subset of $M$ consisting of the elements left fixed by $K$. Let $\varphi$ denote the Brauer character of $M$, which is extended arbitrarily to a class function $\tilde{\varphi}$ on $G$. Then we have

$$
\operatorname{dim}_{F}(M e)=\left(\left.\varphi\right|_{K}, 1_{K}\right)_{K}=\left(\tilde{\varphi}, 1_{K}^{G}\right)_{G}
$$

where $(\cdot, \cdot)_{G}$ denotes the scalar product for class functions. As each Brauer character can be written as a $\mathbb{Z}$-linear combination of ordinary characters restricted to the $p$-regular conjugacy classes, the computation of these scalar products can be carried out entirely in terms of ordinary characters. If the block under consideration is described by a Brauer tree, these linear combinations can directly be read off from the tree.

If $P$ is an $F G$-permutation module on the finite set $\Omega$, then the condensed module $P e$ can be described as follows. Let $\left\{O_{i}\right\}$ be the set of $K$-orbits on $\Omega$, and $\bar{O}_{i}:=\sum_{\omega \in O_{i}} \omega \in P$ be the orbit sums. Then $\left\{\bar{O}_{i}\right\}$ is an $F$-basis of $P e$, and for $g \in G$ the action of ege $\in e F G e$ on $P e$ is given as

$$
\bar{O}_{i} \cdot e g e=\sum_{j} a_{i j}(g) \cdot\left|O_{j}\right|^{-1} \cdot \bar{O}_{j}
$$

where $a_{i j}(g)=\left|\left\{\omega \in O_{i}: \omega g \in O_{j}\right\}\right|$. Hence to find the action of ege, we are reduced to finding the $K$-orbits on $\Omega$, their lengths, and the $a_{i j}(g)$.

### 2.2. The Thompson Group

Now we let $G:=$ Th. For the necessary group theoretic information we refer the reader to [Conway et al. 1985]. We start our constructions with the irreducible representation $D_{248}$ over $\mathbb{F}_{2}$ that is the 2-modular reduction of the irreducible ordinary representation of the same degree. Matrices for the action of two generators $A, B \in G$ on the module underlying $D_{248}$ can be found in the group representation library [Wilson 1996a]. Here, $A$ is a $2 A$ element, $B$ is a $3 A$ element, and their product $A B$ is a $19 A$ element. This is a rationally rigid triple for $G$, see [Wilson 1996b; Pahlings 1990]. The following computations are carried out using $D_{248}$ with the help of the MeatAxe and GAP.

We now let $P_{1}:=A B, P_{2}:=A B^{2}$, and $H:=$ $\left\langle H_{1}, H_{2}\right\rangle$, where

$$
\begin{aligned}
H_{1} & :=\left(P_{1} P_{2} P_{1} P_{2}^{2} P_{1} P_{2}\right)^{2} P_{2} \\
H_{2} & :=\left(H_{1}^{18} P_{1}^{-3} A P_{1}^{3}\right)^{18}
\end{aligned}
$$

Furthermore, we let $K:=\left\langle K_{1}, K_{2}\right\rangle$, where $K_{1}:=$ $H_{1}, K_{2}:=Q_{2} Q_{1} Q_{2}^{-1}$, and

$$
\begin{aligned}
& Q_{1}:=H_{1} H_{2} H_{1} H_{2}^{2}\left(H_{1} H_{2}\right)^{2}\left(H_{1} H_{2}^{2}\right)^{2} \\
& Q_{2}:=\left(H_{2} H_{1}\right)^{2} H_{1}^{3}\left(H_{2} H_{1}\right)^{3}
\end{aligned}
$$

We are going to choose $K$ as our condensation subgroup. Hence we have to show that $|K|$ is not divisible by 19 , and we have to find the scalar products $\left(\chi, 1_{K}^{G}\right)_{G}$ for all irreducible ordinary characters of $G$.

We find that $H_{1}$ is of order 36, and that both $H_{1}, H_{2}$ centralize $H_{1}^{18}$. Hence $H \leq C_{G}\left(H_{1}^{18}\right) \cong$ $2_{+}^{1+8} \cdot A_{9}$. We will show that $H$ equals that centralizer. First we collect a few elements in $H$ generating a normal subgroup $O \leq H$ of order $2^{9}$. Then it turns out that $\left.D_{248}\right|_{H}$ has two different constituents of dimension $8,8 a$ and $8 b$ say, where $8 b$ restricts irreducibly to $K$, while $8 a$ has a fixed space of dimension 1 . Now the vector fixed by $K$
yields an orbit of length 120 under the action of $H$, yielding a permutation representation $P_{120}$ of $H$. This permutation group turns out to be of order $181440=\left|A_{9}\right|$. As $O$ is contained in the kernel of $P_{120}$, we conclude that $H=C_{G}\left(H_{1}^{18}\right)$.

By construction, we know that $K$ is contained in a subgroup $2_{+}^{1+8} . L_{2}(8): 3$ of $H$, which is of index 120 in $H$. Using the action of $\left.D_{248}\right|_{K}$ on an orbit of a suitable vector, we find that $|K| \geq 774144$, hence we have $K \cong 2_{+}^{1+8} . L_{2}(8): 3$.

To compute the scalar products $\left(\chi, 1_{K}^{G}\right)_{G}$, we first observe that $\left(\chi, 1_{K}^{G}\right)_{G}=\left(\chi_{H}, 1_{K}^{H}\right)$ holds. The character tables of $G$ and $H$ are accessible in GAP, and it turns out that the fusion map of the conjugacy classes of $H$ into those of $G$ is uniquely determined up to table automorphisms of $G$. Furthermore, as the normal subgroup $O$ of $H$ is contained in $K$, it is enough to find the fusion map from $L_{2}(8): 3$ to $A_{9}$, which is induced by the fusion map from $K$ to $H$. Hence we choose a factor fusion map from the character table of $H$ to that of $A_{9}$. Having fixed such a map, the admissible table automorphisms of $A_{9}$ are those that leave the chosen fusion map invariant. It now turns out that there are exactly two possible fusion maps from $L_{2}(8): 3$ to $A_{9}$, and these are not conjugate under the action of the admissible table automorphisms. A look at

TABLE 3. Two-permutation characters of $G$. A star in the second column indicates a character in the principal block of $F G$. The columns headed $H$ and $K$ give the scalar products $\left(\chi, 1_{H}^{G}\right)_{G}$ and $\left(\chi, 1_{K}^{G}\right)_{G}$, respectively.

In fact there is no reason why $\mathcal{K}$ should not be equal to $e F G e$, but we do not know whether this is the case. Using the MeatAxe, with the two matrices $M_{e A e}$ and $M_{e B e}$, we find the $\mathcal{K}$-constituents of $P e$. Their dimensions and their multiplicities are given in Table 4.

TABLE 4. Results of condensation.

### 2.3. Proof of the Result

We have to decide between two possible Brauer trees for the principal 19-block of $G$. The first possibility, Case I, is the tree given in Figure 1, which will turn out to be the correct one. The second possibility, Case II, is given in Figure 2.

The degrees of the irreducible Brauer characters $\varphi_{i}$ in the principal block and the dimensions $d_{i}$ of the corresponding condensed modules for Case I

FIGURE 2. The second candidate (Case II) for the Brauer Tree mod 19 of Th.
are given in Table 5. They can be computed from the Brauer tree and Table 3. For example, in Case I, $\varphi_{44}=\chi_{44}-\chi_{25}+\chi_{1}$ on 19-regular elements of $G$. Hence $d_{44}=111-15+1=97$. In Case II, $\varphi_{35}, \varphi_{36}$ have degree 20586123 and $\varphi_{44}$ has degree 64302617 , and we have $d_{35}=d_{36}=25$ and $d_{44}=87$. All other degrees and dimensions remain unchanged.

| Char. | Degree | $d_{i}$ |  |  |  | Char. | Degree |
| :--- | ---: | ---: | ---: | :--- | ---: | ---: | ---: |
|  | $d_{i}$ |  |  |  |  |  |  |
| $\varphi_{1}$ | 1 | 1 |  | $\varphi_{23}$ | 4096000 | 5 |  |
| $\varphi_{2}$ | 248 | $\cdot$ |  | $\varphi_{25}$ | 4881383 | 14 |  |
| $\varphi_{4}$ | 27000 | $\cdot$ |  | $\varphi_{26}$ | 4936502 | 8 |  |
| $\varphi_{5}$ | 27000 | $\cdot$ |  | $\varphi_{29}$ | 6696000 | 6 |  |
| $\varphi_{9}$ | 8599 | - |  | $\varphi_{30}$ | 6696000 | 6 |  |
| $\varphi_{10}$ | 8595 | - |  | $\varphi_{35}$ | 16490123 | 20 |  |
| $\varphi_{12}$ | 740637 | 2 |  | $\varphi_{36}$ | 16490123 | 20 |  |
| $\varphi_{13}$ | 740637 | 2 |  | $\varphi_{43}$ | 71335123 | 87 |  |
| $\varphi_{22}$ | 4096000 | 5 |  | $\varphi_{44}$ | 72494617 | 97 |  |

TABLE 5. Degrees of the irreducible Brauer characters (Case I).

By Tables 3 and 5, the $e F G e$-module $P e$ has unique composition factors of degrees 147 and 119, respectively. These correspond to the two defect 0 characters $\chi_{46}$ and $\chi_{47}$. All other $e F G e$-composition factors of $P e$ have a smaller dimension, in fact at most 97 . It now follows from Table 4, that the irreducible eFGe-modules of dimensions 147 and 119 restrict irreducibly to $\mathcal{K}$. Finally, Table 4 shows that there is an $e F G e$-composition factor of $P e$ of dimension at least 97 , different from the ones of dimensions 147 and 119. This implies that Case I is correct.

## 3. COMPUTATIONS

The key idea of the condensation method applied here is due to Parker and Wilson (private communication). It consists in using the interpretation of the abstract set $\Omega$, where $G$ acts on $\Omega$ as a set of vectors in a space. This gives us a compact and efficient way to compute the $K$-orbits and the action of group elements $g \in G$. A fuller discussion of
this method is contained in [Cooperman and Tselman 1996]. The program from that description was used as the base, but performance enhancements, modifications for robustness and ease of use, and checkpointing facilities had to be added to make it work for the case of $G=$ Th in its 248-dimensional representation $D_{248}$ over $\mathbb{F}_{2}$, where the set $\Omega$ consists of 976841775 vectors and $K \cong 2_{+}^{1+8} . L_{2}(8): 3$ has order 774144 . This section concentrates on these implementation issues.

### 3.1. The Algorithm

The vectors in $\mathbb{F}_{2}^{248}$ are stored with eight entries per byte. So, a vector requires 31 bytes. Since the machines having been used have 64 -bit words, the vectors are in fact stored in 32 bytes each. Matrixvector multiplication over $\mathbb{F}_{2}$ is implemented using logical bit operations. A lookup table of all linear combinations of each set of four adjacent rows un$\operatorname{der} \mathbb{F}_{2}$ is kept for each matrix. Such a lookup table was first used by Arlazarov et al. [Aho et al. 1975; Arlazarov et al. 1970, p. 245], and was popularized by Parker [1984] in his software for the MeatAxe.

The natural algorithm would have been to maintain a hash table for all the 976841775 vectors in $\Omega$. Each vector would be stored in the table, along with an index indicating which $K$-orbit it comes from. At 32 bytes per vector, plus hash table overhead, this would imply the use of more than 32 gigabytes, which would be far from possible at our site. The solution is to store only $1 / m$ of the vectors, where $m=64$ in our case, thus allowing the entire computation to proceed within the available virtual memory. This is accomplished by applying a second hash-like function, and by saving in the hash table only those vectors for which the function returns zero modulo $m$. There are a few small orbits that do not have such vectors. In the case of such orbits, all of the vectors are stored in the hash table. Since $K$ has order 774144 , it is always feasible to place all vectors of a single orbit into a temporary hash table of size less than 32 megabytes.

This decision to store only some of the vectors affects another part of the natural algorithm. At several stages in the algorithm, one must determine if a new vector, $\omega g$, has previously been encountered, and if it has been encountered, what is the index of the orbit to which it belongs. The new solution requires one to do a local search of vectors in the orbit $\omega g K$ until one either finds a vector whose second hash value is 0 modulo $m$, or else until all vectors of the orbit $\omega g K$ have been found. At this point, one has found a vector $\omega^{\prime}$ in the same orbit as $\omega g$. Either $\omega^{\prime}$ is contained in the main hash table, and one can look up the index of the orbit, or one adds $\omega^{\prime}$ to a queue of representatives of new orbits to be explored. Note that one is able to determine a vector that should be contained in the hash table even without having access to the hash table. This is an important point in Section 3.2, where the distributed version of the algorithm is described.

The other complication of the implementation was the decision whether to first store the vectors in the hash table, and then compute the matrix entries $a_{i j}$ (see Section 2.1) or else to compute both at once. For efficiency reasons, it was decided to compute the two at the same time. Thus, when an image vector $\omega g$ is computed, one next determines whether a vector from the corresponding orbit is in the hash table. If this is the case, one increments the appropriate $a_{i j}$ entry. But if it was not part of a known orbit, when does one increment an appropriate $a_{i j}$ ? Further, one must be careful that the number of images $\omega g$ in the queue representing new orbits does not grow too large. This is especially worrisome at the beginning, when many points of new orbits are found, and for an unknown orbit there may be a large number of member vectors waiting in the queue. Ensuring proper accounting and memory restrictions is what leads to complications. The same code is then used to condense the second and further matrices, maintaining the orbit data structures found during the condensation of the first matrix.

### 3.2. Parallelization

Parallelization was carried out through a masterslave architecture. The code was much simplified by the use of the STAR/MPI software [Cooperman 1995], a transaction-oriented parallel LISP. The computation used GCL Common LISP. This parallel tool is based on the MPICH implementation of MPI. At Northeastern University, a small "homegrown" subset of MPI has been implemented by one of us (G. C.) and R. Kyzas as a teaching tool, which replaced MPICH in part of the computations. This software helped to handle such concurrency issues as when two distinct slaves were exploring the same orbit with two distinct orbit representatives from the queue of new orbits.

### 3.3. Timing

The computations were done using eight 175 MHz Alpha 3000/300 workstations at Northeastern University. While the seven slave workstations had 64 megabytes and 300 megabytes of virtual memory, the master had 192 megabytes and 1 gigabyte of virtual memory, timing tests indicate that a matrix-vector multiplication costs about $23 \mu \mathrm{~s}$. The computation took about one month on eight workstations. The calculation was roughly divided into 10 days to determine the orbits, 10 days for the condensation of the first generator with respect to those orbits, and 10 days for the second generator. The first two parts of the computation were mixed together, as described in Section 3.1, although the majority of the first 10 days was still spent in building new orbits and the majority of the second 10 days in computing the condensation of the first generator.

There are two constraints on the speed of the computation: the number of slaves, or equivalently, the CPU speed of the slaves, and the size of semiconductor memory on the master. Determination of the orbits during the first 10 days was primarily constrained by the available CPU power. This is because the number of matrix-vector multiplications in the computation of the points of an orbit
$O_{i}$ is roughly proportional to $\left|O_{i}\right| k$, where $k$ is the size of the generating set for $K$. Yet, $\left|O_{i}\right| / m$ points are needed to be stored on the master. Thus, the slave carries out $k m$ matrix-vector multiplications for each hash access on the master.

The second phase is constrained both by CPU speed and by available memory on the master. The condensation of a generator with respect to those orbits requires approximately $\left|O_{i}\right| m$ matrix-vector multiplications on average, while $\left|O_{i}\right|$ points need to be accessed on the master from the hash array. Hence the slave carries out $m$ matrix-vector multiplications for each hash access on the master. In addition, in the second phase, the hash table is almost full and one must also update the matrix associated with the condensation. Thus, there are still more demands on memory.

The fastest overall performance was determined by balancing these competing demands of memory and CPU time. It was found empirically that it was advantageous to choose $m$ such that the hash array was larger than RAM, and to accept a certain paging penalty. The memory demands for the hash array were proportional, of course, to $|\Omega| / m$. In our example, $m$ was chosen as 64 , and the hash array occupied 610 Megabytes, including hash overhead.
