6 COMA

7 Definition

8 A Cache-Only Memory Architecture (COMA) is a
9 type of cache-coherent nonuniform memory access
10 (CC-NUMA) architecture. Unlike in a conventional
11 CC-NUMA architecture, in a COMA, every shared-
12 memory module in the machine is a cache, where each
13 memory line has a tag with the line's address and state.
14 As a processor references a line, it transparently brings
15 it to both its private cache(s) and its nearby portion of
16 the NUMA shared memory (*Local Memory*) – possibly
17 displacing a valid line from its local memory. Effectively,
18 each shared-memory module acts as a huge cache mem-
19 ory, giving the name COMA to the architecture. Since
20 the COMA hardware automatically replicates the data
21 and migrates it to the memory module of the node that
22 is currently accessing it, COMA increases the chances of
23 data being available locally. This reduces the possibility
24 of frequent long-latency memory accesses. Effectively,
25 COMA dynamically adapts the shared data layout to the
26 application's reference patterns.

27 Discussion

28 Basic Concepts

29 In a conventional CC-NUMA architecture, each node
30 contains one or more processors with private caches and
31 a memory module that is part of the NUMA shared
32 memory. A page allocated in the memory module of

one node can be accessed by the processors of all other nodes. The physical page number of the page specifies the node where the page is allocated. Such node is referred to as the *Home Node* of the page. The physical address of a memory line includes the physical page number and the offset within that page.

In large machines, fetching a line from a remote memory module can take several times longer than fetching it from the local memory module. Consequently, for an application to attain high performance, the local memory module must satisfy a large fraction of the cache misses. This requires a good placement of the program pages across the different nodes. If the program's memory access patterns are too complicated for the software to understand, individual data structures may not end up being placed in the memory module of the node that access them the most. In addition, when a page contains data structures that are read and written by different processors, it is hard to attain a good page placement.

In a COMA, the hardware can transparently eliminate a certain class of remote memory accesses. COMA does this by turning memory modules into large caches called *Attraction Memory* (AM). When a processor requests a line from a remote memory, the line is inserted in both the processor's cache and the node's AM. A line can be evicted from an AM if another line needs the space. Ideally, with this support, the processor dynamically attracts its working set into its local memory module. The lines the processor is not accessing overflow and are sent to other memories. Because a large AM is more capable of containing a node's current working set than a cache is, more of the cache misses are satisfied locally within the node.

There are three issues that need to be addressed in COMA, namely finding a line, replacing a line, and dealing with the memory overhead. In the rest of this article, these issues are described first, then different COMA designs are outlined, and finally further readings are suggested.

73 Finding a Memory Line

74 In a COMA, the address of a memory line is a global
 75 identifier, not an indicator of the line's physical location
 76 in memory. Just like a normal cache, the AM keeps a tag
 77 with the address and state of the memory line currently
 78 stored in each memory location. On a cache miss, the
 79 memory controller has to look up the tags in the local
 80 AM to determine whether or not the access can be ser-
 81 viced locally. If the line is not in the local AM, a remote
 82 request is issued to locate the block.

83 COMA machines have a mechanism to locate a line
 84 in the system so that the processor can find a valid copy
 85 of the line when a miss occurs in the local AM. Differ-
 86 ent mechanisms are used by different classes of COMA
 87 machines.

88 One approach is to organize the machine hierarchi-
 89 cally, with the processors at the leaves of the tree. Each
 90 level in the hierarchy includes a directory-like structure,
 91 with information about the status of the lines present in
 92 the subtree extending from the leaves up to that level of
 93 the hierarchy. To find a line, the processing node issues
 94 a request that goes to successively higher levels of the
 95 tree, potentially going all the way to the root. The pro-
 96 cess stops at the level where the subtree contains the line.
 97 This design is called Hierarchical COMA [2, 7].

98 Another approach involves assigning a home node
 99 to each memory line, based on the line's physical
 100 address. The line's home has the directory entry for the
 101 line. Memory lines can freely migrate, but directory
 102 entries do not. Consequently, to locate a memory line,
 103 a processor interrogates the directory in the line's home
 104 node. The directory always knows the state and location
 105 of the line and can forward the request to the right node.
 106 This design is called Flat COMA [12].

107 Replacing a Memory Line

108 The AM acts as a cache, and lines can be displaced
 109 from it. When a line is displaced in a plain cache, it is
 110 either overwritten (if it is unmodified) or written back
 111 to its home memory module, which guarantees a place
 112 for the line.

113 A memory line in COMA does not have a fixed
 114 backup location where it can be written to if it gets
 115 displaced from an AM. Moreover, even an unmodified
 116 line can be the only copy of that memory line in the
 117 system, and it must not be lost on an AM displace-
 118 ment. Therefore, the system must keep track of the last

copy of a line. As a result, when a modified or other-
 119 wise unique line is displaced from an AM, it must be
 120 relocated into another AM.
 121

To guarantee that at least one copy of an unmodi-
 122 fied line remains in the system, one of the line's copies is
 123 denoted as the *Master* copy. All other shared copies can
 124 be overwritten if displaced, but the master copy must
 125 always be relocated to another AM. When a master copy
 126 or a modified line is relocated, the problem is decid-
 127 ing which node should take the line in its AM. If other
 128 nodes already have one or more other shared copies of
 129 the line, one of them becomes the master copy. Other-
 130 wise, another node must accept the line. This process is
 131 called *Line Injection*.
 132

Different line injection algorithms are possible. One
 133 approach is for the displacing node to send requests to
 134 other nodes asking if they have space to host the line [7].
 135 Another approach is to force one node to accept the line.
 136 This, however, may lead to another line displacement.
 137 A proposed solution is to relocate the new line to the
 138 node that supplied the line that caused the displacement
 139 in the first place [8].
 140

Dealing with Memory Overhead

141 A CC-NUMA machine can allocate all memory to
 142 application or system pages. COMA, however, leaves a
 143 portion of the memory unallocated to facilitate auto-
 144 matic data replication and migration. This unallocated
 145 space supports the replication of lines across AMs.
 146 It also enhances line migration to the AMs of the ref-
 147 erencing nodes because less line relocation traffic is
 148 needed.
 149

Without unallocated space, every time a line is
 150 inserted in the AM, another line would have to be relo-
 151 cated. The ratio between the allocated data size and the
 152 total size of the AMs is called the *Memory Pressure*. If the
 153 memory pressure is 80%, then 20% of the AM space is
 154 available for data replication. Both the relocation traffic
 155 and the number of AM misses increase with the mem-
 156 ory pressure [8]. For a given memory size, choosing an
 157 appropriate memory pressure is a trade-off between the
 158 effect on page faults, AM misses, and relocation traffic.
 159

160 Different Cache-Only Memory Architecture 161 Designs

162 Hierarchical COMA

163 The first designs of COMA machines follow what has
164 been called Hierarchical COMA. These designs orga-
165 nize the machine hierarchically, connecting the proces-
166 sors to the leaves of the tree. These machines include
167 the KSR-1 [2] from Kendall Square Research, which has
168 a hierarchy of rings, and the Data Diffusion Machine
169 (DDM) [7] from the Swedish Institute of Computer
170 Science, which has a hierarchy of buses.

171 Each level in the tree hierarchy includes a directory-
172 like structure, with information about the status of the
173 lines extending from the leaves up to that level of the
174 hierarchy. To find a line, the processing node issues a
175 request that goes to successively higher levels of the tree,
176 potentially going all the way to the root. The process
177 stops at the level where the subtree contains the line.

178 In these designs, substantial latency occurs as the
179 memory requests go up the hierarchy and then down
180 to find the desired line. It has been argued that such
181 latency can offset the potential gains of COMA relative
182 to conventional CC-NUMA architectures [12].

183 Flat COMA

184 A design called Flat COMA makes it easy to locate a
185 memory line by assigning a home node to each memory
186 line [12] – based on the line's physical address. The line's
187 home has the directory entry for the line, like in a con-
188 ventional CC-NUMA architecture. The memory lines
189 can freely migrate, but the directory entries of the mem-
190 ory lines are fixed in their home nodes. At a miss on a
191 line in an AM, a request goes to the node that is keeping
192 the directory information about the line. The directory
193 redirects the request to another node if the home does
194 not have a copy of the line. In Flat COMA, unlike in a
195 conventional CC-NUMA architecture, the home node
196 may not have a copy of the line even though no pro-
197 cessor has written to the line. The line has simply been
198 displaced from the AM in the home node.

199 Because Flat COMA does not rely on a hierarchy to
200 find a block, it can use any high-speed network.

201 Simple COMA

202 A design called Simple COMA (S-COMA) [10] transfers
203 some of the complexity in the AM line displacement and

relocation mechanisms to software. The general coher- 204
ence actions, however, are still maintained in hard- 205
ware for performance reasons. Specifically, in S-COMA, 206
the operating system sets aside space in the AM for 207
incoming memory blocks on a page- granularity basis. 208
The local Memory Management Unit (MMU) has map- 209
pings only for pages in the local node, not for remote 210
pages. When a node accesses for the first time a shared 211
page that is already in a remote node, the processor suf- 212
fers a page fault. The operating system then allocates a 213
page frame locally for the requested line. Thereafter, the 214
hardware continues with the request, including locating 215
a valid copy of the line and inserting it, in the cor- 216
rect state, in the newly allocated page in the local AM. 217
The rest of the page remains unused until future 218
requests to other lines of the page start filling it. Sub- 219
sequent accesses to the line get their mapping directly 220
from the MMU. There are no AM address tags to check 221
if the correct line is accessed. 222

Since the physical address used to identify a line in 223
the AM is set up independently by the MMU in each 224
node, two copies of the same line in different nodes are 225
likely to have different physical addresses. Shared data 226
needs a global identity so that different nodes can com- 227
municate. To this end, each node has a translation table 228
that converts local addresses to global identifiers and 229
vice versa. 230

231 Multiplexed Simple COMA

S-COMA sets aside memory space in page-sized 232
chunks, even if only one line of each page is present. 233
Consequently, S-COMA suffers from memory frag- 234
mentation. This can cause programs to have inflated 235
working sets that overflow the AM, inducing frequent 236
page replacements and resulting in high operating sys- 237
tem overhead and poor performance. 238

Multiplexed Simple COMA (MS-COMA) [1] elim- 239
inates this problem by allowing multiple virtual pages 240
in a given node to map to the same physical page at 241
the same time. This mapping is possible because all the 242
lines on a virtual page are not used at the same time. 243
A given physical page can now contain lines belonging 244
to different virtual pages if each line has a short vir- 245
tual page ID. If two lines belonging to different pages 246
have the same page offset, they displace each other 247
from the AM. The overall result is a compression of the 248
application's working set. 249

250 Further Readings

251 There are several papers that discuss COMA and
 252 related topics. Dahlgren and Torrellas present a more
 253 in-depth survey of COMA machine issues [3]. There
 254 are several designs that combine COMA and con-
 255 ventional CC-NUMA architecture features, such as
 256 NUMA with Remote Caches (NUMA-RC) [9], Reactive
 257 NUMA [5], Excel-NUMA [14], the Sun Microsystems'
 258 WildFire multiprocessor design [6], the IBM Prism
 259 architecture [4], and the Illinois I-ACOMA architecture
 260 [13]. A model for comparing the performance of COMA
 261 and conventional CC-NUMA architectures is presented
 262 by Zhang and Torrellas [15]. Soundarajan et al. [11]
 263 describe the trade-offs related to data migration and
 264 replication in CC-NUMA machines.
