Abstract

The SPEC benchmark suite consists of ten public-domain, non-trivial programs that are widely used to measure the performance of computer systems, particularly those in the Unix workstation market. These benchmarks were expressly chosen to represent real-world applications and were intended to be large enough to stress the computational and memory system resources of current-generation machines. The extent to which the *SPECmark* (the figure of merit obtained from running the SPEC benchmarks under certain specified conditions) accurately represents performance with live real workloads is not well established; in particular, there is some question whether the memory referencing behavior (cache performance) is appropriate.

In this paper, we present measurements of miss ratios for the entire set of SPEC benchmarks for a variety of CPU cache configurations; this study extends earlier work that measured only the performance of the integer (C) SPEC benchmarks. We find that instruction cache miss ratios are generally very low, and that data cache miss ratios for the integer benchmarks are also quite low. Data cache miss ratios for the floating point benchmarks are more in line with published measurements for real workloads. We believe that the discrepancy between the SPEC benchmark miss ratios and those observed elsewhere is partially due to the fact that the SPEC benchmarks are all almost exclusively user state CPU benchmarks run until completion as the single active user process. We therefore believe that SPECmark performance levels may not reflect system performance when there is multiprogramming, time sharing and/or significant operating systems activity.

1. Introduction

The SPEC benchmarks [SPEC89,90, Scot90] are a selection of non-trivial programs chosen to standardize benchmarking. SPEC (System Performance Evaluation Consortium) assembled this suite to provide a standard set of realistic benchmarks for inter-system comparisons; see [Pric89, Hinn88] for a discussion of the many problems with the benchmarking situation prior to SPEC. Several factors, including strong industrial support for SPEC, the realistic nature of the benchmarks, and acceptable code portability have led to the wide use of these programs for benchmarking purposes. To improve verification and reproducibility of results, SPEC benchmark results must include a description of any source code modifications, compiler and operating system release numbers, machine characteristics, and most other factors that can affect the reported results. The SPEC benchmarks have become so important as a measure of CPU performance that some system developers are parameterizing their designs to maximize SPEC benchmark performance, even when this might lead to lower performance on other, perhaps more realistic, workloads. Similarly, compiler writers have been concentrating on producing good code for the frequently executed inner loops of some of the SPEC benchmarks, such as *matrix300*. Recent very high SPEC benchmark results for *matrix300* show the success of their efforts.

SPEC Benchmark Suite		
Program	Language	Description
doduc	Fortran	Thermohydraulic simulation of a nuclear reactor
eqntott	C	Builds truth table from a boolean expression
espresso	C	Boolean function minimization
fpppp	Fortran	Two electron integral derivative
gcc	C	GNU C compiler compiling pre-processed source files
matrix300	Fortran	Linpack SAXPY routine on 300x300 matrix
nasa7	Fortran	Seven floating-point synthetic kernels
spice	Fortran	Analog circuit simulator
tomcatv	Fortran	Mesh generation program
xlisp	C	Lisp interpreter solving eight queens problem

Table 1: SPEC Benchmark Applications

Release 1.0 of the SPEC benchmarks consists of four integer-intensive C programs (*eqntott*, *espresso*, *gcc*, and *xlisp*) and six floating-point intensive Fortran programs (*doduc*, *fpppp*, *matrix300*, *nasa7*, *spice*, and *tomcatv*). The SPEC benchmarking procedure is to run each program to completion on the target system, with only one user process active, and then take the ratio of that run time to the run time of the same program on a DEC VAX 11/780. The geometric mean of those ratios, averaged over the SPEC benchmark suite, yields the "*SPECmark*", which is a single number figure of merit. Table 1 lists and gives a short description of each benchmark.

As noted above, considerable effort is being expended on creating computer systems (hardware and software) to optimize SPEC benchmark results. Two questions therefore arise: (a) In what ways should the system be designed to perform well on the SPEC benchmark suite? (b) Is this a good idea?

One important aspect of CPU performance, and probably the most important of the architectural aspects (as opposed to technology parameters, such as circuit speed) is the performance of the memory hierarchy. We note that SPEC benchmark results are quite sensitive to cache size, as may be seen by comparing the various published measurements of systems with varying caches sizes based on the Motorola 88000. In terms of the SPEC benchmarks, the two questions above become: (a) What miss ratios can be expected when running the SPEC benchmarks on a cache of a given design? (b) Are these miss ratios comparable to those for “typical” user workloads, for some definition of typical?

In this paper we present measurements of the cache miss ratios of the entire SPEC benchmark suite and comment on their potential use in the design of caches and memory hierarchies. We compare the SPEC cache miss ratios to design target miss ratios [Smit87], miss ratios measured using hardware monitors at Amdahl [Smit82] and on DEC VAX-series machines [Clar83,88], miss ratios observed from very long address traces [Borg90], and other miss ratios that include operating system and multiprogramming behavior. We also note that miss ratios for multiprogrammed workloads with significant operating system activity are known to be high [Agar88,Ande91].

2. SPEC Cache Performance

2.1. Methodology

We compiled and ran the SPEC programs on DECstation 3100’s (which contain the MIPS R2000 microprocessor), running version 4.1 of the DEC Ultrix operating system. We used version 2.0 of the C compiler and version 2.1 of the Fortran compiler with optimization level -O3 for espresso, doduc, nasa7 xlisp, eqntott, matrix300, fpppp, tomcatv and -O2 for gcc, spice as per the SPEC Makefiles. Note that we have not used any of the recently developed preprocessors which have been very successful in reorganizing the data references for Matrix300. We then used the MIPS *pixie* [DEC91] tool to generate address traces to feed directly to the *tycho* [Hill] cache simulator. Pixie modifies the compiled code to generate a trace record for each load, store and basic block entry; trace records for all instruction fetches are then constructed from the basic block records. Tycho uses algorithms that, for a given block size, simulate all cache sizes and associativities in a single pass through an address trace [Hill87].

We varied cache size from 1 Kbyte to 1 Mbyte, set size from one (direct-mapped) to eight, and block size from 16 to 256 bytes. All caches used the LRU replacement algorithm and the lowest order available address bits to select the set. We simulated instruction, data, and unified caches, without any periodic cache flushing, as the SPEC benchmarks are typically run in a uniprogrammed environment. Miss ratios represent the complete execution of a benchmark and include start-up as well as steady-state effects. The

use of *pixie* to generate address traces allows simulation of only user, and not system references, and our data is for user code only. Table 2 lists the number of instruction, data, and total user memory references made by each program. Note that the trace reflects a 4-byte memory interface; the trace would be different for a different memory interface width. Note also that the trace includes only actual program loads, stores and instruction fetches; it does not include the extra memory activity such as instruction prefetch that would occur on most machines [Clar83].

Program	Instruction	Data	Total
eqntott	1,241,913,236	215,772,134	1,457,685,370
espresso	3,143,686,831	696,870,530	3,840,557,361
gcc	1,262,492,069	398,952,157	1,661,444,226
xlisp	1,234,252,567	457,209,682	1,691,462,249
doduc	1,619,374,300	583,667,566	2,203,041,866
fpppp	2,396,679,406	1,514,694,293	3,911,373,699
matrix300	2,766,534,109	1,311,922,365	4,078,456,474
nasa7	9,195,719,149	4,720,515,938	13,916,235,087
spice	28,696,843,509	8,288,246,353	36,985,089,862
tomcatv	1,872,460,468	913,221,318	2,785,681,786

Table 2: Program Reference Counts

To increase our confidence in our results we compared them with two other studies that ran the SPEC benchmarks on a MIPS R2000 microprocessor. Pnevmatikatos and Hill [Pnev90] presented cache miss ratios for the four integer (C language) SPEC benchmarks. They used a different compiler (gcc) and a tracing methodology that excludes library references. Nevertheless, most miss ratio differences are less than 0.01. In few cases, however, a seemingly small miss ratio difference translates into a substantial relative change. We are inclined to place the most confidence in the results presented here, since this analysis has used much more mature and sophisticated compilers, but the comparison demonstrates that cache miss ratios, instruction counts, and related measures are, as might be expected, sensitive to the compiler used. We must thus caution readers that *your actual mileage may vary*. Cmelik et al. [Cmel91] give instruction counts for SPEC benchmarks. With two exceptions, Xlisp and Spice, their counts are close to ours. For Xlisp, the instruction count difference is due to different input files; we solved the eight queens problem, while they solved the nine queens problem. For Spice, however, we cannot explain the difference, although simulation runs at both Berkeley and Madison yielded consistent results.

Simulating these caches required 400 to 800 microseconds of CPU time per memory reference in each trace. Assuming an average 600 microseconds per memory reference, simulating all ten SPEC benchmarks requires some 500 days or *nearly 17 months* of CPU time. Including false starts, simulation errors, and operating system

bugs, we used *two to three years of machine time* to compute our results; this type of measurement would not have been possible if it had been necessary to pay for CPU time on a timeshared machine. With five machines available for running simulations at Berkeley and Madison, we were able to generate these results in less than six months of calendar time.

2.2. Results

The appendix of this paper displays the miss ratios for each SPEC program, for each block (line) size from 16 to 256 bytes, each cache size from 4Kbytes to 1Mbyte, for set-associativity of 1 (direct mapping), 2, 4 and 8, and for instruction, data and unified caches.[†] In this section, we comment on some of that data.

We first examine instruction cache miss ratios for the different programs. For *eqntott*, *matrix300*, *nasa7*, and *tomcatv*, instruction cache miss ratios are very low, generally less than 0.0001 for caches as small as a few kilobytes. These programs spend much of their execution time in a few small routines; *matrix300*, for example, spends about 99% of its execution time in one small basic block in the code [Saav90,Saav91]. Miss ratios for *espresso*, *xlisp*, and *spice* are only slightly larger, as miss ratios again fall below 0.0001 for cache sizes as small as 16 or 32 Kbytes. Instruction cache miss ratios are largest for *doduc*, *gcc*, and *fpppp*, yet are well below half a percent for caches as small as 64 or 128 Kbytes. None of the SPEC benchmarks makes significant use of more than 128 Kbytes of instruction cache.

Miss ratios for data caches are larger, especially for several of the floating-point Fortran benchmarks, but for the most part are quite low as cache size approaches one megabyte. Miss ratios for *xlisp* and *doduc* are the lowest among the SPEC suite, dropping below one percent for caches as small as 16 or 32 Kbytes, and falling below 0.0001 for a 64 Kbyte cache. Results for *fpppp* and *espresso* are nearly as low as results for *xlisp* and *doduc* when set size is greater than one, and somewhat larger for direct-mapped caches. Among the integer programs, *eqntott* and *gcc* exercise fairly large data caches; miss ratios remain above one percent until cache size reaches 512 Kbytes.

The floating-point programs *matrix300*, *nasa7*, *spice*, and *tomcatv* exhibit the largest data cache miss ratios. Miss ratios for *matrix300*, *nasa7*, and *spice* are several percent until the cache size reaches one megabyte, causing miss rates to fall below one percent. *Tomcatv* requires extremely large caches when the cache block size is small. Data cache miss ratios are *over 6 percent* for a 1 Mbyte cache at a 16-byte block size. Each successive doubling of block size in *tomcatv* at 1Mbyte reduces data cache miss ratios by almost half, and miss ratios do become less than one percent for a 128 byte block size.

Unified (data and instruction) cache miss ratios usually fall between instruction and data cache miss ratios, as the strong locality in instruction references offsets the weaker locality in data references. We do observe several instances where unified cache miss rates are *higher* than corresponding data cache miss rates (*espresso*, *xlisp*, *doduc*, *fpppp*).

[†] See the appendix for a description of how to obtain an electronic copy of these results.

This behavior occurs mainly at larger cache sizes coupled with low associativities, and where separate instruction and data cache miss ratios have fallen to nearly zero. The low associativity causes instruction and data references to conflict for cache sets, while such conflicts do not occur in separate instruction and data caches. Note that a split direct-mapped instruction/data cache pair is more like a 2-way set-associative unified cache than a direct-mapped unified cache.

It is worth noting that there are a few anomalies in the data with respect to the effect of associativity on miss ratio. Generally, miss ratios decrease with increased degrees of set associativity, since the probability of mapping conflicts decreases [Hill89]. It is possible, however, that miss ratios can increase with increasing associativity if certain reference patterns are present in the memory reference string; we note just that effect at one or more data points for the fpppp, matrix300, spice, tomcatv, and doduc miss ratios. These anomalies are disturbing in that they suggest, incorrectly, that on the average miss ratios will not decrease with increasing associativity.

3. Evaluation

In this section we compare the SPEC miss ratios with miss ratios from previous studies and discuss whether the SPEC applications make suitable cache benchmarks. We first describe the other studies.

- (a) Smith [Smit82] includes several measurements taken with a hardware monitor at Amdahl Corporation on various models of the Amdahl 470V machines. Results showed that supervisor state miss ratios were much higher than problem state miss ratios, and that the miss ratio for each of user and supervisor state could be approximated by equations of the form $m = a * k^b$, where a and b are constants and k is the cache size in kilobytes.
- (b) Two studies [Clar83,88] provide cache miss ratios taken via hardware measurement from VAX 11/780 and VAX 8800 computers. The 11/780 has an 8 Kbyte, write-through unified cache with an 8-byte block size and a set size of two. The 8800 has a 64 Kbyte, write-through, direct-mapped unified cache with a 64-byte block size.
- (c) Smith [Smit85] introduced the *design target miss ratios (DTMRs)* to represent typical levels of performance, averaged over a wide class of workloads, ranging from workstations to timeshared mainframes. He synthesized them from real (hardware monitor) measurements that existed in the literature and a large number of trace-driven simulation results. The initial DTMRs for 16-byte line size, fully-associative caches [Smit85] were later extended to other line sizes [Smit87] and to set-associative caches [Hill87,89].
- (d) Agarwal, et al. [Agar88] presented miss ratios that include the effects of operating system references and multiprogramming by using microcode to capture address traces from multi-tasked machines. These effects can more than double miss rates from those measured in a uniprogrammed, user-only environment.

- (e) Borg, et al. [Borg90] generated miss ratios for very long address traces using tools similar to our own; those traces were over twelve billion memory references long. The traces were used to evaluate the performance of a variety of caches.

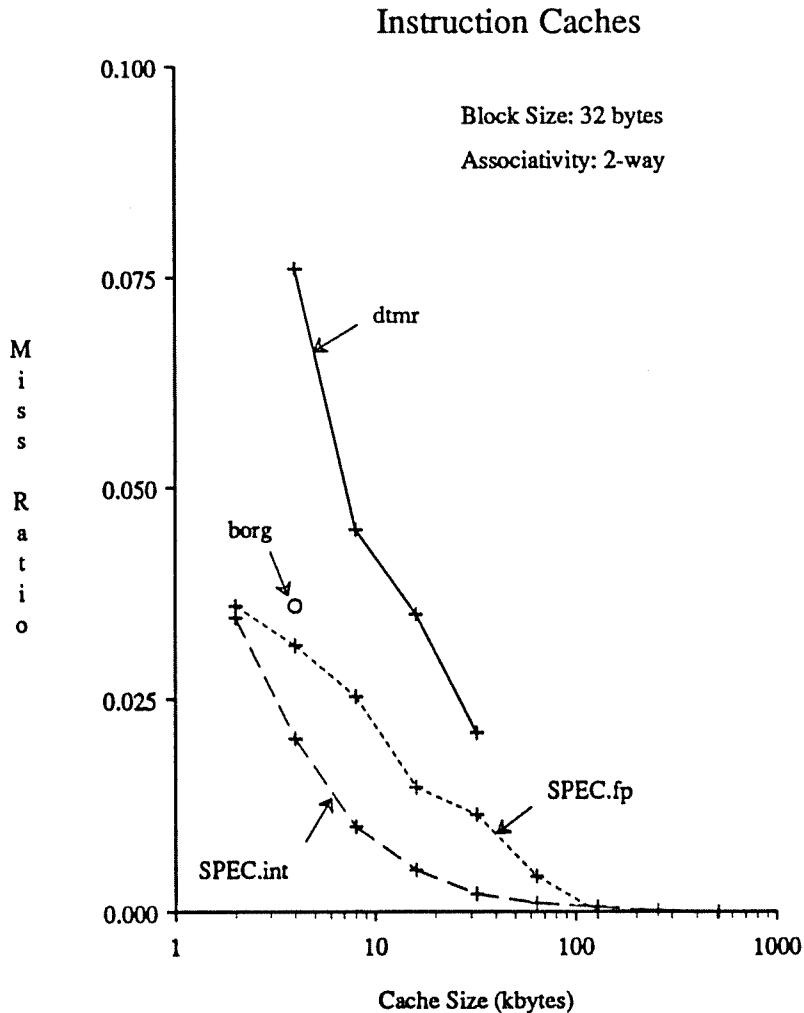

Figure 1: Instruction cache miss ratios

Figures 1 through 3 show average SPEC miss ratios for instruction, data, and unified caches, with 32-byte lines and 2-way set-associativity, computed separately for the integer and floating-point benchmarks. We also list in Tables 3 through 5 average miss ratios for the integer, floating-point, and complete SPEC suite across the entire range of simulation parameters. These averages represent the unweighted arithmetic mean of individual program miss ratios, similar to how the SPECmark represents the geometric mean of individual program SPECratios. In Figures 1 and 2, averages miss rates are plotted against the design target miss ratios (labeled *dtmr*) and primary cache miss ratios from [Borg90] for a multiprogrammed workload (labeled *borg*). Unfortunately, miss ratios from the other studies are not available for separate instruction and data caches, but are plotted against SPEC unified cache results in Figure 3. Previous results based on

different block sizes (VAX 11/780, VAX 8800, Agarwal, et al.) or different associativities (VAX 8800, Borg et al.) are adjusted for these parameters using ratios of miss ratios from prior studies [Hill89, Smit87].

A look at Figure 1 suggests that instruction cache miss ratios for the SPEC benchmarks are highly optimistic, as they are as low as one-third of the design target miss ratios and one-half of Borg's miss ratios.

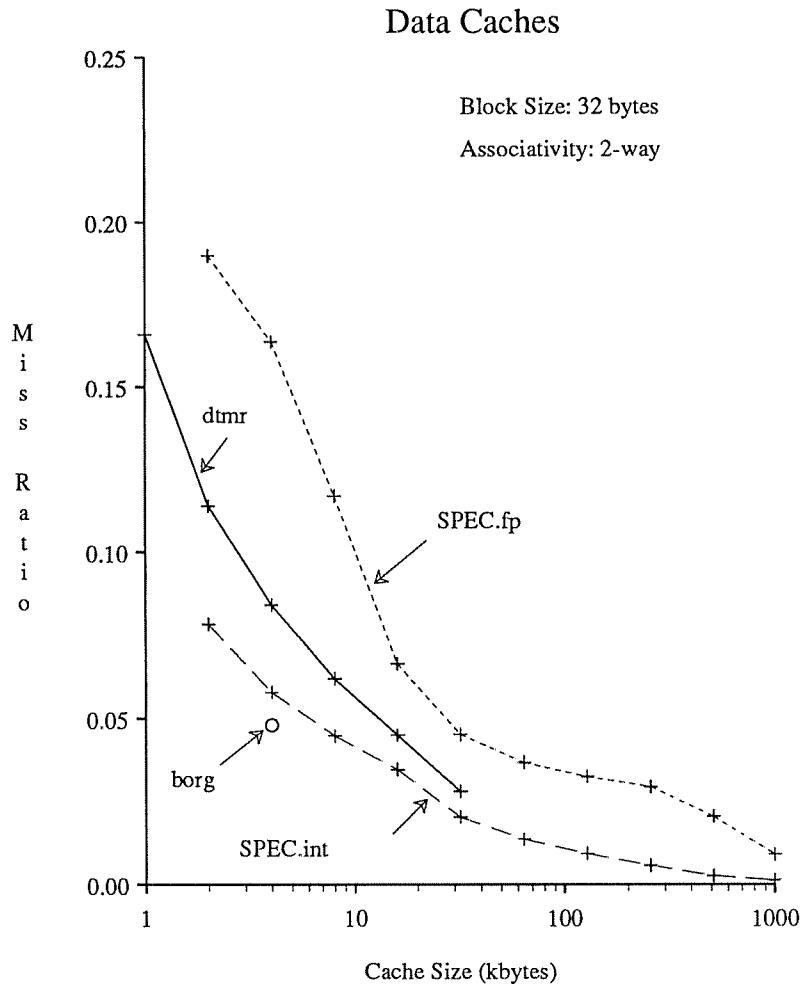

Figure 2: Data cache miss ratios

In Figure 2, we see that data cache miss ratios for the SPEC integer and floating point benchmarks bracket the DTMRs; both are above the [Borg90] measurements. Both sets of SPEC benchmarks approach zero miss ratio for large caches, a phenomenon that might not occur for a time sharing workload where programs task switch many times before completing.

Figure 3 contains unified cache measurements from the various other studies in addition to SPEC and design target miss ratios. These include: Amdahl 470 supervisor and user state miss ratios (plots labeled *470.sup* and *470.user*), VAX 11/780 and VAX 8800 miss ratios (plots labeled *VAX.780* and *VAX.8800*), and miss ratios from [Agar88] for a multiprogramming level of 3 (plots labeled *agarwal.mul3*). (We plot the Amdahl data from the fitted curve in [Smit82]; the original data points are not available.) We note that the VAX8800 data was collected from a very heavily used timeshared system. The Amdahl 470 supervisor data was collected from the execution of a standard internal Amdahl commercial workload. For both the VAX8800 and Amdahl data, the level of supervisor activity was quite high. Following in decreasing order of miss ratio are the DTMRs, the SPEC floating point miss ratios, and Agarwal's multiprogrammed miss ratios. VAX 11/780 and Amdahl 470 user state miss ratios follow, and the SPEC integer miss rates are smallest by a wide margin.

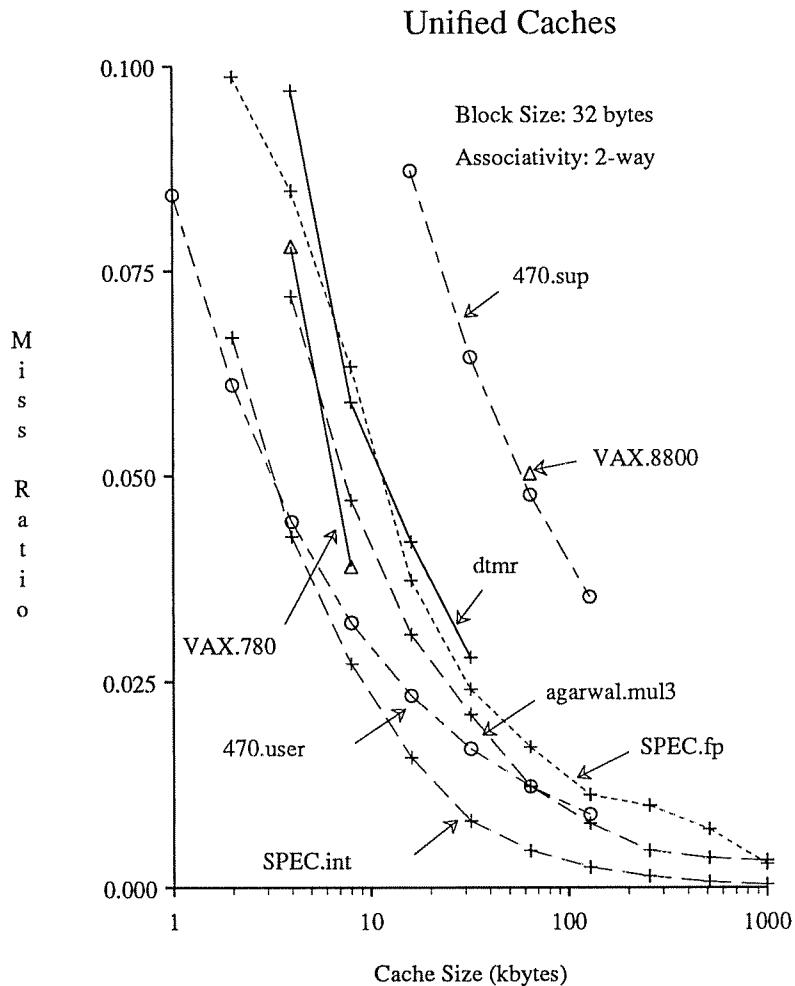

Figure 3: Unified cache miss ratios

Table 3: Average miss ratios for the integer SPEC benchmarks.

All of the data in the literature (see e.g. [Smit82], [Ande91], [Agar88]) suggests that operating systems activity significantly increases miss ratios. First, operating systems code tends to loop less than user code, and so instruction miss ratios are high. Second, operating systems routines are usually called into the cache by an exception, interrupt or trap, then run for a short time, and finally are replaced from the cache before they run again; they effectively always face a "cold start" situation. Sanguinetti observes [Sang84] that for the Amdahl 580, routines must execute over 600 times per second to stay cache resident. Third, operating system activity is associated with timesharing and high levels of multiprogramming; frequent task switching means that programs are constantly experiencing cold start. As illustrated by Figure 3, miss ratios for the SPEC benchmarks are considerably below those for any workloads with significant OS activity. Similar differences in cache performance between compute bound and multiprogrammed environments are reported in [Mogu91]. The SPEC floating-point benchmark miss ratios are quite close to the DTMRs, the data from [Agar88], and the VAX 11/780 measurements, and for large cache sizes are also very close to the Amdahl 470 user program miss ratios. The SPEC integer benchmark miss ratios are lowest.

4. Conclusions

The purpose of this study is two-fold: to show measurements of the cache performance of the SPEC benchmarks and to comment on the usefulness of those benchmarks for cache and memory system design. While the cache performance of the SPEC benchmarks varies from program to program, we have found that the floating-point benchmarks generally require much larger cache sizes relative to the integer benchmarks. The integer benchmarks use no more than 128 Kbytes of instruction and 128 Kbytes of data cache, while the floating-point programs can take advantage of data caches of a megabyte or more.

Comparisons with other studies suggest that the SPEC integer benchmarks are too small to represent real workloads. Miss ratios for the SPEC floating-point benchmarks seem consistent with previous measurements of user program miss ratios but are quite low relative to supervisor code miss ratios.

>From these measurements and comparisons, we conclude that miss ratios for the SPEC benchmarks are potentially typical of only a certain environment - Unix workstations running user state CPU bound jobs as the single active user process. The integer benchmarks have very low miss ratios, and provide very little stress on the memory system. The floating point benchmarks provide reasonable measurements of memory system performance for user code, but are still much better behaved than commercial and timeshared workloads. The SPEC benchmarks are conspicuously lacking a significant operating system component, which affects their validity in two ways: miss ratios are too low, and the performance impacts of operating systems functions themselves are not tested.

Appendix[†]

Disclaimer: Data in this appendix is correct to the best of our knowledge. However, we provide it *as is* without an expressed or implied warranty, and we accept no responsibility for the consequences of the use or misuse of this data.
