ABSTRACT

Data centers supporting current cloud-based services are characterized by a huge number of hardware and software resources, often cooperating in complex and unpredictable ways. Understanding the state of these systems for management and service level agreement reasons requires novel monitoring architectures because fully centralized systems do not scale to the required number of flows while pure peer-to-peer architectures cannot provide a global view of the system's internal state. To make matters worse, these services should be provided over short, quasi real-time intervals. We propose a novel monitoring architecture that, by combining a hierarchical approach with decentralized monitors, addresses the aforementioned challenges. We evaluate its scalability by means of an analytical models that is validated through a set of experimental results.

Index Terms—Large Scale; Distributed; Data Center; Monitoring; Cloud; Scalability.

I. INTRODUCTION

Cloud Computing is the most used model to support the processing of large data volumes using clusters of commodity computers. For example, according to [1], already in 2008 Google processed about 20 petabytes of data per day through an average of 100.000 MapReduce jobs spread across approximately 400 machines in September 2007, crunching 11.000 machine years in a single month. This dramatic increase in resource utilization is not unique to Google, but rather to most competitors in the cloud computing arena. As of late 2010, Hadoop [2] clusters at Yahoo span 25000 servers, and store 25 petabytes of application data, with the

largest cluster being 3500 servers [3]. Cloud SQL Server uses Microsoft SQL Azure [4] to deploy an Internet scale relational database service viable to clusters of thousands of nodes.

These large infrastructures are monitored through a multitude of services that extract and store measurements about the performance and the utilization of specific hardware and software resources. The resource sampling interval is usually kept constant and described in terms of its frequency. The behavior of each resource can be described through the tuple (resource name, sampling interval, time series). In this paper, we refer to this tuple with the name *resource data stream*. For example, Sony uses the closed-source Zyrion Traverse database [5] to claim the monitoring of over 6000 devices and applications over twelve datacenters across Asia, Europe and North America. The virtual data layer within the solution collects half a million resource data streams every five minutes. This scenario opens important challenges in the design of an advanced monitoring infrastructure:

- 1) it must be able to *scale to at least one million* of heterogeneous resource data streams within reasonable real-time constraints which will not be uncommon in the near future;
- 2) it *must not have any single point of failure* to ensure service continuity.

We state that none of the existing solutions fully addresses all these issues. In particular, fully centralized monitors cannot scale to the desired number of resource data streams. For example, the prototype system introduced in [6], which uses Ganglia and Syslog-NG to accumulate data into a central

MySQL database, shows severe scalability limits at only 64 monitored nodes, each one collecting 20 metrics every 30 seconds. Here, the main bottleneck is related to the increasing computational overhead occurring at high sampling frequencies. On the other hand, lowering the sampling frequency (commonly, once every five minutes) can make it difficult to spot rapidly changing workloads. Current decentralized, per-data-center, hierarchical monitors such as Ganglia [7] are limited to computing efficiently averages of measures spanning over several nodes. However, the complexity of current workloads in modern data centers calls for more sophisticated processing, such as the identification of correlations among different resource data streams, or the detection of anomalies in the global system state. Finally, the vast majority of current monitoring infrastructures, including OpenNMS [8], Zabbix [9], Zenoss [10] and Cacti [11] are not designed to be resilient to failures. If, for any reason, any software module fails (due to a bug, insufficient computing resources, human mistake) it must be restarted manually. In a very large system it is surprisingly easy for a system administrator to miss these failures and to keep a monitor running incorrectly (and producing garbage resource data streams) for extended periods of time.

To address these challenges, in this paper we propose an architecture for monitoring large-scale network infrastructures hosted in data centers. Each data center is equipped with its own decoupled monitoring infrastructure; each monitor adopts a hierarchical scheme to ensure scalability with respect to the number of monitored resources. The internal operations of the monitor are geared towards two objectives: to provide real-time access to single performance samples or graphs, and reduce the expected time for the user to retrieve more sophisticated analysis. The latter goal is obtained through a batch-oriented subsystem that will be detailed in the following section. Every single component in the infrastructure is designed to be resilient to failures. In particular, whenever possible, we enrich the existing software modules with redundancy and failover mechanisms. Otherwise, we automatically restart the modules in case of failure.

Due to reasons of space, in this paper we focus only on the local acquisition and analysis subsystem and leave the other discussion to a future paper.

Our preliminary analysis reveals that the per-cluster architecture is able to:

- collect 2946 resource data streams (from 128 probes) on a single monitored node every second with a resources utilization $<10\%$;
- collect 377088 resource data streams per second from 128 different monitored nodes using a single collector node;
- collect and process over three millions resource data streams per second.

The rest of this paper is organized as follows. Section II describes the design decisions supporting the aforementioned requirements, provides the architecture of the monitoring infrastructure, motivates the choice of the software components and discusses various implementation details. Section III investigates the theoretical scalability limits of the proposed architecture. Section IV evaluates the current state-of-the-art in the area of large-scale system monitoring. Finally, Section V concludes the paper with some remarks.

II. ARCHITECTURE DESIGN

The early decisions that have inspired the design of the proposed architecture share two important goals: to dominate the complexity of the monitoring problem and to avoid single points of failure. The huge problem size makes it literally impossible to deploy any kind of centralized infrastructure. Even worse, service centralization would not be fault-tolerant. For these reasons, each cluster is equipped with an independent monitor infrastructure. In our opinion, this is the only viable alternative to scaling to an arbitrary number of data centers. This strategy is carried out only in the most advanced hierarchical monitoring systems.

In order to scale to millions of data streams per sample interval, it is mandatory to shift preliminary computations (such as the sampling of a resource and performing sanity checks on the sampled data) as close as possible to the edge of the monitored infrastructure. Failure to do so would result in a system that unnecessarily processes potentially useless data. Ideally, the resource data streams should be initially filtered (or marked as invalid, anomalous) on the monitored nodes. The resulting streams can be sent to a storage system. This approach scales because the checks are, usually, computationally inex-

pensive and the monitored nodes are, usually, much more than those dedicated to the monitoring infrastructure. Pushing frequent and preliminary checks towards the edge of the monitored infrastructure is currently done by Ganglia and Astrolabe [12]. Since the size of the sampled data is a crucial factor in large monitoring systems that can severely impact the network bandwidth, we also perform live compression of the resource data streams.

Every time new samples are added to the resource data stream, an extra overhead is paid due to data storage. As previous literature shows, in this scenario characterized by frequent, small, random database requests [13], write operations to secondary storage do suffer from scalability issues. To reduce this overhead, write operations should be grouped and batched to secondary storage. We believe that the map-reduce paradigm [14] is well suited to this purpose. The adoption of map-reduce also allows to perform sophisticated analysis over the collected resource data streams in a scalable fashion with commodity hardware (or even in a leased platform such as Amazon EC2). On the other hand, the most advanced monitors compute at most moving averages of regular windows of past samples. To the best of our knowledge, this paper represents one first step towards a richer analysis in a quasi real-time scenario.

To avoid single points of failure and to ensure service continuity, we enforce redundancy of every component of the monitoring architecture. Whenever possible, we deploy our solutions using software that can be easily replicated. In other cases, we wrap the component through custom scripts that detect failures and restart it, in case.

At the lowest level of infrastructure, a set of hardware and software resources can be associated to subnets, racks, distinct production areas, and logical or physical clusters. Each resource is monitored by a probe process that is responsible for collecting periodically performance and/or utilization samples. On each monitored node, a collection agent receives the samples from several probes, performs preliminary validity checks on them, updates the resource data streams and sends them in a coded form (usually, a compression) to a dedicated collector node.

The collector node is the main component of the distributed cluster data filter. It receives the

filtered and coded resource data streams, performs the necessary decompression and stores them for further analysis or a real-time plot. In the latter case, processing stops and the user is able to see immediately the behavior of the resource data stream. In the former case, data is made available to the distributed analyzer system. Its purpose is to compute more sophisticated models on the resource data streams, such as identification of the relevant components in the system, trend analysis, anomaly detection and capacity planning. The goal of these actions is to provide a “reduced view” of the entire cluster by discarding the negligible data streams in terms of system management. At the end of the analysis, the resulting resource data streams are persistently stored and available as (key, value) pairs, where “key” is a unique identifier of a measure and “value” is usually a tuple of values describing it (for example timestamp, host name, service/process, name of the monitored performance index, actual value).

Fig. 1. Monitored node

We have used exclusively open source tools that can be modified and adapted for our goals. The operating system adopted in the prototype is GNU/Linux (we used Debian, Ubuntu and Fedora in different experimental testbeds), enhanced with the software packages from the Cloudera repository (CDH4). The languages used for the deployment of our modules are Bash (v4.2.36) and C (where efficiency is needed, such as in our modified monitor probes). The batch processing framework is Hadoop [2], version 2.0. Our choice is motivated by the dramatic scalability improvement with respect to traditional RDBMS-based data storage architec-

tures under random, write intensive data access patterns [15]. Other frameworks like Traverse [5] and Microsoft SQL Azure [4] are proprietary, or are not adequate to supports long-term network growth [7], [16].

The collection agent. Each monitored node (scheme in Figure 1) is equipped with an independent collection agent. Its main duty is to ensure that each hardware and software resource of interest is continuously monitored. To this purpose, each resource has associated a probe process that collects a set of indexes (such as response time, throughput and utilization) at constant time intervals. Both parameters (performance indexes and sampling interval) are fully configurable by the user. Probing is performed through standard, off-the-shelf monitoring tools (vmstat, pidstat, sar); the associated performance indexes include CPU utilization, disk and network bandwidth, number of page faults and memory usage, both per-process and system-wide. We have modified the nethogs code to measure also per-process bandwidth consumption, which was natively not available in batch form. The output of each probe process is piped into a C program (called agent). This module keeps a constant, configurable window of past samples representing the resource data stream and performs preliminary sanity checks on it. These checks are executed through dynamic, pluggable modules that receive in input the data stream and respond with TRUE or FALSE. If at least one check fails, the stream is tagged as invalid, but it is never discarded; this facilitates later debugging operations. Currently, the following checks are implemented: missing value, value out of range, sequence of null values. The pre-processed streams are coded (in our prototype, GZIP-compressed) and finally forwarded to the selected monitor node of the distributed cluster data filter. The selection of the monitor node is made by a specific module of the agent (Figure 1, *comm.s*), which ensure the best monitor choice and the relative availability. This choice is made on the basis of reachability and the workload of the collector nodes. For this purpose, each monitored node knows a subset of all collector nodes in the cluster. Each sample has the following record format:

```
<index> <timestamp> <value> <monitored host> <tag> .. <tag>
```

where “index” is the name of the desired performance or utilization index, “timestamp” is the sampling instant in UNIX time format, “value” is the sampled value returned from the probe, “monitored host” is the symbolic name or the IP address of the host executing the probe, and “tag” is an information cookie of the form “name=value” that enriches the description (there can be multiple tags). Some example records are displayed below:

```
block.in 1345742145 3 host=webserver12 check=true
cpu.user 1345742115 9 host=node67 check=true
gproc.net.rxkB/s 1345742120 3.21000003814 iface=eth0
host=client45 pid=1130 name=apache2 check=true
```

Each component (probe, agent) is wrapped by a BASH script that restarts it in case of exit with an error status. After a preconfigured number of restart failures, a warning alert is sent to the administrator of the corresponding service.

Fig. 2. Cluster collection, filtering and analysis

The distributed cluster data filter. The resource data streams gathered by the collection agent are sent to the Distributed cluster data filter, shown in Figure 2. Here, a collector process receives the compressed and filtered resource data streams. The received streams are decoded and sent to two

different storage: one for real-time plotting of the resource data streams, and one for later, non-real-time processing. If needs be, several collectors can be added to scale the acquisition process to the desired number of resource data streams. The collector is designed to scale up to thousands of streams, provided that the limitations on the maximum number of TCP connections and open files be raised. In GNU/Linux, this can be easily achieved by recompiling the Linux kernel and the GNU C library.

The former storage is handled by OpenTSDB [17], a software for the storage and configurable plotting of time series. We have chosen OpenTSDB because it is open-source, scalable, and interacts with another open-source distributed database, HBase [18]. It retains time series for a configurable amount of time (defaults to forever), it creates custom graphs on the fly, it allows to plug it into an alerting system such as Nagios [19]. The OpenTSDB's secret ingredient that helps to increase its reliability, scalability and efficiency is *asynchbase*. It is a fully asynchronous, non-blocking HBase [18] client, written from the ground up to be thread-safe for server apps. It has far fewer threads and far less lock contention; it uses less memory and provides more throughput especially for write-heavy workloads. The latter storage, called data sync, receives data destined to further processing, performed by the following subsystem. To enhance the performance of the storage engine, we have chosen to pack the resource data streams in larger chunks (64KB by default) and write them asynchronously to a distributed file system that can be scaled to the appropriate size by easily adding backend nodes. The distributed file system we have chosen is the Hadoop Distributed File System (HDFS). It creates multiple replicas of data blocks and distributes them on compute nodes throughout a cluster to enable reliable, extremely scalable computations. It is also designed to run on commodity hardware, is highly fault-tolerant, provides high throughput access to application data and is suitable for applications that have large data sets.

The distributed analyzer system. The distributed analyzer system is composed by a set of analyzer nodes (Figure 2). Each analyzer node runs

arbitrary batch jobs that analyze the resource data streams. Typical analyses include:

- 1) computing moving averages of resource data streams, in order to provide a more stable representation of an internal resource's status;
- 2) correlating several resource state representations in order to exclude secondary flows;
- 3) computing prediction trends of resource representations on different time scales.

The batch jobs first read the necessary resource data streams (*map*) from the distributed cluster data filter and runs the appropriate scripts (*reduce*). The result is a reduced set of (key, value) pairs that is written to the distributed data storage. The goal shared by these operations is to compute a reduced state information that is able to tell whether the service is about to misbehave or not and, in the former case, also to tell which resource is the culprit. The different analyzer functions also produce the status of each node and cluster, and few figures of merit that show the health status of the entire data center (longer term predictions, principal component analysis, capacity planning).

We have chosen the Pig framework for the implementation of the analysis scripts. Pig offers richer data structures over pure map-reduce, for example multivalued and nested dictionaries. Each Pig script is compiled into a series of equivalent map-reduce scripts that process the input data and write the results in a parallel way. We implemented scripts to aggregate data both temporally and spatially (over nodes). Further analysis include anomaly detections, trend analysis and supports for capacity planning on a longer time scale.

The distributed data storage. The reduced streams representing the system state must be written into a database. The data storage must scale with an increasing number of data streams, must be fault tolerant and should be oriented to time series management. We have chosen Apache HBase [18] as the distributed analysis storage for many reasons, which include the homogeneity and the reuse of components. Apache HBase is a distributed column-oriented database built on top of HDFS, designed from the ground-up to scale linearly just by adding nodes. It is not relational and does not support SQL, but thanks to the proper space management properties, it is able to surpass a traditional RDBMS-based

system by hosting very large and sparsely populated tables on clusters implemented on commodity hardware. In our architecture, the HBase storage is responsible to preserve all the analyzed information about nodes, clusters and datacenter.

III. ANALYSIS

In this section we evaluate the scalability of the proposed architectures in terms of number of monitored resource data streams. In particular, we find out:

- how many resource data streams can be monitored per physical host (intra-node scalability);
- how many physical hosts can be monitored (inter-node scalability).

We have used two different hardware platforms, Amazon EC2 and Emulab. In the next paragraphs we will only present the results on the Amazon EC2 platform, due to high similarity with Emulab ones. The backing storage is shared across the instances (EBS). The theoretical network connectivity is up to 1Gbps. The virtual machines are running instances of the popular TPC-W benchmark suite (one for client, one for the application server, one for the DBMS). The application server is Tomcat (v6.0), while the DBMS is MySQL (v5.1). In the monitored node, one probe is dedicated to system-related performance monitoring (essentially, through the output of the vmstat and sar monitors). The remaining probes are process-related (through the output of the pidstat and nethogs2 monitors). This system probe collects 25 difference performance indexes, while each process probe collects 23 different metrics. The sampling interval is configured at $t = 1s$ for each probe.

TABLE I
AVERAGE RESOURCE UTILIZATION OF THE COLLECTION AGENT

Number of probes	Number of metrics	CPU (%)	Main memory (%)	Network (%)
1	25	0.3	0.4	0.005
2	48	0.5	0.5	0.009
4	94	1.1	0.6	0.019
8	186	1.8	0.9	0.041
16	370	2.9	1.4	0.085
32	738	4.1	2.6	0.173
64	1474	6.0	4.8	0.352
128	2946	9.8	9.3	0.681
256	5890	23.1	18.3	1.392

A. Intra-node scalability

In this first scenario, we evaluate how many resource data streams (metrics) can be handled on a single monitored node. We use one collector node and one analyzer node running a single script that computes the moving average for every resource data stream. The detail of the resources of the monitored node is the following: micro instance, 613 MB memory, Up to 2 EC2 Compute Units (Dual-Core AMD Opteron(tm) Processor 2218 HE, cpu 2600 MHz, cache size 1024 KB), EBS storage, dedicated network bandwidth of 100 Mbps per node.

Table I reports the average resource consumption of the collection agent as a function of the number of resource data streams monitored. From the table we see that the most used resources is the CPU. At 128 probes, the CPU utilization is about the 10%. This threshold is commonly used as the largest fraction of resource utilization that administrators are comfortable devoting to monitoring. Lacking any more principled standard, we have adopted this as our target maximum resource utilization for the monitoring system. Thus, on a single monitored node, it is reasonable to collect 128 probes for a total of 2946 resource data streams per second.

B. Inter-node scalability

In the next experiment, we add monitored nodes with the same probe setup and measure the resource consumption of the collector and the analyzer node.

Table II reports the average resource consumption of the collector and analyzer nodes as a function of the number of the monitored nodes. From the table we see that the most used resource is the CPU of the collector node. We have run experiments up to a maximum of the most used resources is the CPU (mainly due to the decompression effort of multiple heterogeneous packets). At 128 monitored hosts, the CPU of the collector node is saturated. In this scenario, the system is monitoring $128 * 128 = 16384$ resource data streams and $2946 * 128 = 377088$ metrics.

We have added collector nodes and incremented the number of monitored hosts to evaluate the scalability of the distributed cluster data filter. Table III reports the average resource utilization across the collector nodes.

TABLE II
AVERAGE RESOURCE UTILIZATION OF THE COLLECTOR AND THE ANALYZER NODE

Number of monitored nodes	Number of data streams	Number of metrics	CPU collector	Network collector	CPU analyzer	Network analyzer
1	128	2946	0.6	0.450	0.1	0.023
2	256	5892	0.9	0.899	0.1	0.037
4	512	11784	2.0	1.797	0.2	0.089
8	1024	23568	3.6	3.594	0.3	0.176
16	2048	47136	8.1	7.188	0.7	0.341
32	4096	94272	17.1	14.375	1.8	0.702
64	8192	188544	33.6	28.750	2.5	1.597
128	16384	377088	69.9	57.500	5.2	2.996

TABLE III
AVERAGE RESOURCE UTILIZATION OVER THE DISTRIBUTED CLUSTER DATA FILTER

Number of monitored nodes	Number of data streams	Number of metrics	Number of collector nodes	CPU collector (AVG)	Network collector (AVG)	CPU analyzer (AVG)	Network analyzer (AVG)
128	16384	377088	1	69.6	57.539	5.2	2.996
256	32768	754176	2	70.4	57.890	6.2	3.209
512	65536	1508352	4	71.1	58.020	5.5	3.007
1024	131072	3016704	8	70.7	57.970	5.1	2.891

We kept adding collectors up to 1024 monitored nodes. We also had to add more HDFS and HBASE nodes to support the write throughput after 256 nodes. In this scenario, one hour of experiment produces more than 30 GB of data only for the real-time subsystem, monitoring $128 * 1024 = 131072$ different streams per second (or about 130000 different processes). We have also measured the total network bandwidth in about 60 MB/s and we have monitored $2946 * 1024 = 3016704$ metrics.

IV. RELATED WORK

The oldest log collection framework is syslog, which supports streaming logs across the network. System activity report is another popular system monitor used on most UNIX-like systems. Hawk-eye [20] is a monitor for grid systems. Nagios [19] and Cacti [11] are a popular alerting and monitoring system respectively, which has inspired, among the others, OpenNMS [8], Zabbix [9], Zenoss [10], GroundWorks [21] and Hyperic [22]. Hyperic is currently collecting and analyzing more than 9000 resources and 11000 metrics per minute at hi5, hundreds of servers with different OSs and applications which produce more than 6500 metrics per minute at MOSSO, and more than 37000 resources and 20000 metrics per minute at CONTEGIX. Zabbix claims the monitoring of up-to 100000 monitored

devices and up-to one million of metrics (no time unit is reported), and thousands of checks per second. It requires a database (MySQL, PostgreSQL, Oracle or SQLite) to store the collected metrics. Zenoss currently manages networks as large as 32,000 devices. These and other centralized products alone cannot cope with the challenges presented in this paper. In particular, their scalability is often severely hindered by a RDBMS backend, they cannot be easily balanced, they are not designed to be fault tolerant. In other words, centralized solutions represent a serious scalability bottleneck and introduce single point of failure.

The rise of datacenter-scale distributed systems has made these problems particularly glaring, and in recent years several newer hierarchical systems have been developed, among these Ganglia [7]. Hierarchical monitors overcome some of the limitations of centralized solutions at the cost of overall system manageability, which now depends on different site specific administrators. Further, the root node in the system may present a single point failure similar to the centralized model.

Astrolabe [12] is a hybrid solution that combines a hierarchical scheme with an unstructured P2P routing protocol for distributed communication. While it is highly scalable and resilient, its manageability is a complex task since it incurs a lot

of network traffic. Unstructured systems do not put any constraints on placement of data items on peers and how peers maintain their network connections. Resource lookup queries are flooded to the directly connected peers, which in turn flood their neighboring peers. Queries have a TTL (Time to Live) field associated with maximum number of hops, and suffer from non-deterministic result, high network communication overload and non-scalability [23].

V. CONCLUSIONS

In this paper, we have proposed a novel architecture for monitoring large-scale network infrastructures hosted in data centers. These choices are mandatory when you have to support gathering and analysis operations of huge numbers of data streams coming from cloud system monitors. The proposed architecture is already integrated with on-line analyzers working at different temporal scales. Our preliminary experiments show the potential scalability limits of the monitoring system: more than 3M of resource data streams per data center, per second. All these operations of data streams are carried out within real-time constraints in the order of seconds thus demonstrating that huge margins of improvement are feasible.

We are currently studying an hybrid solution (both hierarchical and peer-to-peer) in a WAN emulated scenario. Finally, we are studying adaptive random sampling techniques to further reduce the number of performance samples collected at each monitored node.
