# A GENERALIZATION OF RESOURCE-BOUNDED MEASURE, WITH APPLICATION TO THE BPP VS. EXP PROBLEM* 

HARRY BUHRMAN ${ }^{\dagger}$, DIETER VAN MELKEBEEK ${ }^{\ddagger}$, KENNETH W. REGAN ${ }^{\S}$, D. SIVAKUMAR ${ }^{\circledR}$, AND MARTIN STRAUSS ${ }^{\|}$

#### Abstract

We introduce resource-bounded betting games and propose a generalization of Lutz's resource-bounded measure in which the choice of the next string to bet on is fully adaptive. Lutz's martingales are equivalent to betting games constrained to bet on strings in lexicographic order. We show that if strong pseudorandom number generators exist, then betting games are equivalent to martingales for measure on E and EXP. However, we construct betting games that succeed on certain classes whose Lutz measures are important open problems: the class of polynomial-time Turingcomplete languages in EXP and its superclass of polynomial-time Turing-autoreducible languages. If an EXP-martingale succeeds on either of these classes, or if betting games have the "finite union property" possessed by Lutz's measure, one obtains the nonrelativizable consequence BPP $\neq$ EXP. We also show that if EXP $\neq$ MA, then the polynomial-time truth-table-autoreducible languages have Lutz measure zero, whereas if $\mathrm{EXP}=\mathrm{BPP}$, they have measure one.

1. Introduction. Lutz's theory of measure on complexity classes is now usually defined in terms of resource-bounded martingales. A martingale can be regarded as a gambling game played on unseen languages $A$. Let $s_{1}, s_{2}, s_{3}, \ldots$ be the standard lexicographic ordering of strings. The gambler $G$ starts with capital $C_{0}=\$ 1$ and places a bet $B_{1} \in\left[0, C_{0}\right]$ on either " $s_{1} \in A$ " or " $s_{1} \notin A$." Given a fixed particular language $A$, the bet's outcome depends only on whether $s_{1} \in A$. If the bet wins, then the new capital $C_{1}$ equals $C_{0}+B_{1}$, while if the bet loses, $C_{1}=C_{0}-B_{1}$. The gambler then places a bet $B_{2} \in\left[0, C_{1}\right]$ on (or against) membership of the string $s_{2}$, then on

[^0]$s_{3}$, and so forth. The gambler succeeds if $G$ 's capital $C_{i}$ grows toward $+\infty$. The class $\mathcal{C}$ of languages $A$ on which $G$ succeeds (and any subclass) is said to have measure zero. One also says $G$ covers $\mathcal{C}$. Lutz and others (see [Lutz97]) have developed a rich and extensive theory around this measure-zero notion and have shown interesting connections to many other important problems in complexity theory.

We propose the generalization obtained by lifting the requirement that $G$ must bet on strings in lexicographic order. That is, $G$ may begin by choosing any string $x_{1}$ on which to place its first bet and, after the oracle tells the result, may choose any other string $x_{2}$ for its second bet, and so forth. Note that the sequences $x_{1}, x_{2}, x_{3}, \ldots$ (as well as $B_{1}, B_{2}, B_{3}, \ldots$ ) may be radically different for different oracle languages $A$-in complexity-theory parlance, $G$ 's queries are adaptive. The lone restriction is that $G$ may not query (or bet on) the same string twice. We call $G$ a betting game.

Our betting games remedy a possible lack in the martingale theory, one best explained in the context of languages that are "random" for classes $\mathcal{D}$ such as E or EXP. In this paper, E stands for deterministic time $2^{O(n)}$, and EXP stands for deterministic time $2^{n^{O(1)}}$. A language $L$ is $\mathcal{D}$-random if $L$ cannot be covered by a $\mathcal{D}$-martingale. Based on one's intuition about random 0-1 sequences, the language $L^{\prime}=\{\operatorname{fip}(x): x \in L\}$ should likewise be $\mathcal{D}$-random, where $\operatorname{flip}(x)$ changes every 0 in $x$ to a 1 and vice-versa. However, this closure property is not known for Erandom or EXP-random languages, because of the way martingales are tied to the fixed lexicographic ordering of $\Sigma^{*}$. Betting games can adapt to easy permutations of $\Sigma^{*}$ such as that induced by flip. Similarly, a class $\mathcal{C}$ that is small in the sense of being covered by a ( $\mathcal{D}$-) betting game remains small if the languages $L \in \mathcal{C}$ are so permuted. In the r.e./recursive theory of random languages, our generalization is similar to "Kolmogorov-Loveland place-selection rules" (see [Lov69]). We make this theory work for complexity classes via a novel definition of "running in time $t(n)$ " for an infinite process.

Our new angle on measure theory may be useful for attacking the problem of separating BPP from EXP, which has recently gained prominence in [ImWi98]. In Lutz's theory it is open whether the class of EXP-complete sets-under polynomialtime Turing reductions-has EXP-measure zero. If so (in fact if this set does not have measure one), then by results of Allender and Strauss [AlSt94], BPP $\neq$ EXP. Since there are oracles $A$ such that $\mathrm{BPP}^{A}=\operatorname{EXP}^{A}$ [Hel86], this kind of absolute separation would be a major breakthrough. We show that the EXP-complete sets can be covered by an EXP-betting game - in fact, by an E-betting game. The one technical lack in our theory as a notion of measure is also interesting here: If the "finite unions" property holds for betting games (viz., $\mathcal{C}_{1}$ small $\wedge \mathcal{C}_{2}$ small $\Longrightarrow$ $\mathcal{C}_{1} \cup \mathcal{C}_{2}$ small), then EXP $\neq \mathrm{BPP}$. Likewise, if Lutz's martingales do enjoy the permutation-invariance of betting games, then BPP $\neq$ EXP. Finally, we show that if a pseudorandom number generator of security $2^{n^{\Omega(1)}}$ exists, then for every EXPbetting game $G$ one can find an EXP-martingale that succeeds on all sets covered by $G$. Pseudorandom generators of higher security $2^{\Omega(n)}$ likewise imply the equivalence of E-betting games and E-measure. Ambos-Spies, Lempp, and Mainhardt [ALM98] proved that the EXP-complete sets have E-measure zero under a different hypothesis, namely $\mathrm{P}=\mathrm{PSPACE}$.

Measure theory and betting games help us to dig further into questions about pseudorandom generators and complexity-class separations. Our tool is the notion of an autoreducible set, whose importance in complexity theory was argued by Buhrman, Fortnow, van Melkebeek, and Torenvliet [BFvMT98] (after [BFT95]). A
langnage $L$ is $\leq_{T}^{p}$-autoreducible if there is a polynomial-time oracle Turing machine $Q$ such that for all inputs $x, Q^{L}$ correctly decides whether $x \in L$ without ever submitting $x$ itself as a query to $L$. If $Q$ is nonadaptive (i.e., computes a polynomial-time truth-table reduction), we say $L$ is $\leq_{t t}^{p}$-autoreducible. We show that the class of $\leq_{T}^{p}$-autoreducible sets is covered by an E-betting game. Since every EXP-complete set is $\leq_{T}^{p}$-autoreducible [BFvMT98], this implies results given above. The subclass of $\leq_{t t}^{p}$-autoreducible sets provides the following tighter connection between measure statements and open problems about EXP.

- If the $\leq_{t t}^{p}$-autoreducible sets do not have E -measure zero, then $\mathrm{EXP}=\mathrm{MA}$.
- If the $\leq_{t t}^{p}$-autoreducible sets do not have E-measure one in EXP, then EXP $\neq$ BPP.
Here MA is Babai's "Merlin-Arthur" class, which contains BPP and NP and is contained in the level $\Sigma_{2}^{p} \cap \Pi_{2}^{p}$ of the polynomial hierarchy [Bab85, BaMo88]. Since EXP $\neq$ MA is strongly believed, one would expect the class of $\leq_{t t}^{p}$-autoreducible sets to have E-measure zero, but proving this-or proving any of the dozen other measure statements in Corollaries 6.2 and 6.5 -would yield a proof of EXP $\neq \mathrm{BPP}$.

In sum, the whole theory of resource-bounded measure has progressed far enough to wind the issues of (pseudo)randomness and stochasticity within exponential time very tightly. We turn the wheels a few more notches and seek greater understanding of complexity classes in the places where the boundary between "measure one" and "measure zero" seems tightest.

Section 2 reviews the formal definitions of Lutz's measure and martingales. Section 3 introduces betting games and shows that they are a generalization of martingales. Section 4 shows how to simulate a betting game by a martingale of perhaps unavoidably higher time complexity. Section 5, however, demonstrates that strong pseudorandom generators (if there are any) allow one to compute the martingale in the same order of time. Section 6 presents our main results pertaining to autoreducible sets, including our main motivating example of a concrete betting game. The concluding section 7 summarizes open problems and gives prospects for future research.
2. Martingales. A martingale is abstractly defined as a function $d$ from $\{0,1\}^{*}$ into the nonnegative reals that satisfies the following "average law": for all $w \in$ $\{0,1\}^{*}$.

$$
\begin{equation*}
d(w)=\frac{d(w 0)+d(w 1)}{2} \tag{1}
\end{equation*}
$$

The interpretation in Lutz's theory is that a string $w \in\{0,1\}^{*}$ stands for an initial segment of a language over an arbitrary alphabet $\Sigma$ as follows: Let $s_{1}, s_{2}, s_{3}, \ldots$ be the standard lexicographic ordering of $\Sigma^{*}$. Then for any language $A \subseteq \Sigma^{*}$, write $w \sqsubseteq A$ if for all $i, 1 \leq i \leq|w|, s_{i} \in A$ iff the $i$ th bit of $w$ is a 1 . We also regard $w$ as a function with domain $\operatorname{dom}(w)=\left\{s_{1}, \ldots, s_{|w|}\right\}$ and range $\{0,1\}$, writing $w\left(s_{i}\right)$ for the $i$ th bit of $w$. A martingale $d$ succeeds on a language $A$ if the sequence of values $d(w)$ for $w \sqsubseteq A$ is unbounded.

Let $S^{\infty}[d]$ stand for the (possibly empty, often uncountable) class of languages on which $d$ succeeds. Lutz originally defined the complexity of a martingale $d$ in terms of computing fast-converging rational approximations to $d$. Subsequently he showed that for certain classes of time bounds one loses no generality by requiring that martingales themselves have rational values $a / b$ such that all digits of the integers $a$ and $b$ (not necessarily in lowest terms) are output within the time bound. That
is, given any martingale $d$ meeting the original definition of computability within the time bound, one can obtain a rational-valued $d^{\prime}$ computable within that bound such that $S^{\infty}[d] \subseteq S^{\infty}\left[d^{\prime}\right]$ [May94t, JuLu95]. We adopt this requirement throughout the paper and specify that integers are represented in standard binary notation and rationals as pairs of integers, not necessarily in lowest terms. We use the fact that a sum $a_{1} / b_{1}+\cdots a_{m} / b_{m}$ can be computed and written down in $\ell^{O(1)}$ time, where $\ell$ is the sum of the lengths of the integers $a_{i}$ and $b_{i}$.

Definition 2.1 (cf. [Lutz92, May94t]). Let $\Delta$ be a complexity class of functions. A class $\mathcal{C}$ of languages has $\Delta$-measure zero, written $\mu_{\Delta}(\mathcal{C})=0$, if there is a martingale $d$ computable in $\Delta$ such that $\mathcal{C} \subseteq S^{\infty}[d]$. One also says that $d$ covers $\mathcal{C}$.

Lutz measured the time to compute $d(w)$ in terms of the length $N$ of $w$, but one can also work in terms of the largest length $n$ of a string in the domain of $w$. For $N>0, n$ equals $\left\lfloor\log _{2} N\right\rfloor$; all we care about is that $n=\Theta(\log N)$ and $N=2^{\Theta(n)}$. Because complexity bounds on languages we want to analyze will naturally be stated in terms of $n$, we prefer to use $n$ for martingale complexity bounds. The following correspondence is helpful:

$$
\begin{aligned}
& \text { Lutz's "p" } \sim N^{O(1)}=2^{O(n)} \sim \text { measure on E, } \\
& \text { Lutz's " } p_{2} " \sim 2^{(\log N)^{O(1)}}=2^{n^{O(1)}} \sim \text { measure on EXP. }
\end{aligned}
$$

Since we measure the time to compute $d(w)$ in terms of $n$, we write " $\mu_{\mathrm{E}}$ " for E-measure, " $\mu_{\text {EXP }}$ " for EXP-measure, and generally $\mu_{\Delta}$ for any $\Delta$ that names both a language and function class. Abusing notation similarly, we define the following.

Definition 2.2 (see [Lutz92]). A class $\mathcal{C}$ has $\Delta$-measure one, written $\mu_{\Delta}(\mathcal{C})=1$, if $\mu_{\Delta}(\Delta \backslash \mathcal{C})=0$.

The concept of resource-bounded measure is known to be robust under several changes [May94t]. The following lemma has appeared in various forms [May94t, BuLo00]. It essentially says that we can assume a martingale grows almost monotonically (sure winnings) and not too fast (slow winnings).

Lemma 2.3 ("slow-but-sure-winnings" lemma for martingales). Let d be a martingale. Then there is a martingale $d^{\prime}$ with $S^{\infty}[d] \subseteq S^{\infty}\left[d^{\prime}\right]$ such that

$$
\begin{gather*}
(\forall w)(\forall u): d^{\prime}(w u)>d^{\prime}(w)-2 d(\lambda), \quad \text { and }  \tag{2}\\
(\forall w): d^{\prime}(w)<2(|w|+1) d(\lambda) . \tag{3}
\end{gather*}
$$

If $d$ is computable in time $t(n)$, then $d^{\prime}$ is computable in time $\left(2^{n} t(n)\right)^{O(1)}$.
The idea is to play the strategy of $d$ but in a more conservative way. Say we start with an initial capital of $\$ 1$. We will deposit a part $c$ of our capital in a bank and only play the strategy underlying $d$ on the remaining liquid part $e$ of our capital. We start with no savings and a liquid capital of $\$ 1$. If our liquid capital reaches or exceeds $\$ 2$, we deposit an additional $\$ 1$ or $\$ 2$ to our savings account $c$ so as to keep the liquid capital in the range $\$[1,2)$ at all times. If $d$ succeeds, it will push the liquid capital infinitely often to $\$ 2$ or above, so $c$ grows to infinity, and $d^{\prime}$ succeeds too. Since we never take money out of our savings account $c$ and the liquid capital $e$ is bounded by $\$ 2$, once our total capital $d^{\prime}=c+e$ has reached a certain level, it will never go more than $\$ 2$ below that level anymore, no matter how bad the strategy underlying $d$ is. On the other hand, since we add at most $\$ 2$ to $c$ in each step, $d^{\prime}(w)$ cannot exceed $2(|w|+1)$ either.

We now give the formal proof.
Proof of Lemma 2.3. Define $d^{\prime}: \Sigma^{*} \rightarrow[0, \infty)$ by

$$
d^{\prime}(w)=(c(w)+e(w)) d(\lambda)
$$

where $c(\lambda)=0$ and $e(\lambda)=1$, and

$$
\begin{array}{llll}
c(w b)=c(w) & \text { and } & e(w b)=e(w) & \text { if } d(w)=0 ; \text { else: } \\
c(w b)=c(w)+2 & \text { and } & e(w b)=\frac{d(w b)}{d(w)} e(w)-2 & \text { if } \frac{d(w b)}{d(w)} e(w) \geq 3 ; \\
c(w b)=c(w)+1 & \text { and } & e(w b)=\frac{d w b)}{d(w)} e(w)-1 & \text { if } 2 \leq \frac{d(w b)}{d(w)} e(w)<3 ; \\
c(w b)=c(w) & \text { and } & e(w b)=\frac{d(w b)}{d(w)} e(w) & \text { if } \frac{d(w b)}{d(w)} e(w)<2 .
\end{array}
$$

To see that the recursion does not excessively blow up the time complexity or size of the answer, note that owing to cancellation of values of $d$, every value $e(w)$ where $d(u) \neq 0$ is given by a sum of the form

$$
\sum_{k=0}^{N} a_{k} \frac{d(w)}{d(w[1 \ldots k])}
$$

where each $a_{k}$ is in $\{-2,-1,0,1\}, N=|w|$, and $w[1 \ldots k]$ stands for the first $k$ bits of $u$. Each term in the sum is computable in time $O\left(t(n)^{2} N\right)$ (using the naive quadratic algorithms for multiplication and integer division). Then by the property noted just before Definition 2.1, these terms can be summed in time $(N t(n))^{O(1)}$.

By induction on $|w|$ we observe that

$$
\begin{equation*}
0 \leq e(w)<2 \tag{4}
\end{equation*}
$$

and that

$$
d^{\prime}(w b)= \begin{cases}{\left[c(w)+\frac{d(w b)}{d(w)} e(w)\right] d(\lambda)} & \text { if } d(w) \neq 0 \\ d^{\prime}(w) & \text { otherwise }\end{cases}
$$

from which it follows that $d^{\prime}$ is a martingale.
Now let $\omega$ be an infinite $0-1$ sequence denoting a language on which $d$ succeeds. Then $e(w)$ will always remain positive for $w \sqsubseteq \omega$, and $\frac{d(w b)}{d(w)} e(w)$ will become 2 or more infinitely often. Consequently, $\lim _{w \sqsubseteq \omega,|w| \rightarrow \infty} c(w)=\infty$. Since $d^{\prime}(w) \geq c(w) d(\lambda)$, it follows that $S^{\infty}[d] \subseteq S^{\infty}\left[d^{\prime}\right]$. Moreover, by (4) and the fact that $c$ does not decrease along any sequence, we have that

$$
d^{\prime}\left(w^{\prime} u\right) \geq c\left(u^{\prime} u\right) d(\lambda) \geq c(w) d(\lambda)=d^{\prime}(w)-e(w) d(\lambda)>d^{\prime}(w)-2 d(\lambda)
$$

Since $c$ can increase by at most 2 in every step, $c(w) \leq 2|w|$. Together with (4), this yields that

$$
d^{\prime}(w)=(c(w)+e(w)) d(\lambda)<2(|w|+1) d(\lambda)
$$

One can also show that $S^{\infty}\left[d^{\prime}\right] \subseteq S^{\infty}[d]$ in Lemma 2.3, so the success set actually remains intact under the above transformation.

As with Lebesgue measure, the property of having resource-bounded measure zero is monotone and closed under union ("finite unions property"). A resource-bounded version of closure under countable unions also holds. The property that becomes crucial in resource-bounded measure is that the whole space $\Delta$ does not have measure zero, which Lutz calls the "measure conservation" property. With a slight abuse of meaning for " $\neq$ " this property is written $\mu_{\Delta}(\Delta) \neq 0$. In particular, $\mu_{\mathrm{E}}(\mathrm{E}) \neq 0$ and
$\mu_{\operatorname{EXP}}(\mathrm{EXP}) \neq 0$. Subclasses of $\Delta$ that require substantially fewer resources do have $\Delta$-measure zero. For example, P has E -measure zero. Indeed, for any fixed $c>0$, DTIME $\left[2^{c n}\right]$ has E-measure zero and DTIME $\left[2^{n^{c}}\right]$ has EXP-measure zero [Lutz92].

Apart from formalizing rareness and abundance in computational complexity theory, resource-bounded martingales are also used to define the concept of a random set in a resource-bounded setting.

Definition 2.4. $A$ set $A$ is $\Delta$-random if $\mu_{\Delta}(\{A\}) \neq 0$.
In other words, $A$ is $\Delta$-random if no $\Delta$-martingale succeeds on $A$.
3. Betting games. To capture intuitions that have been expressed not only for Lutz measure but also in many earlier papers on random sequences, we formalize a betting game as an infinite process, rather than as a Turing machine that has finite computations on string inputs.

Definition 3.1. A betting game $G$ is an oracle Turing machine that maintains a "capital tape" and a "bet tape," in addition to its standard query tape and worktapes, and works in stages $i=1,2,3 \ldots$ as follows. Beginning each stage $i$, the capital tape holds a nonnegative rational number $C_{i-1}$. The initial capital $C_{0}$ is some positive rational number. $G$ computes a query string $x_{i}$ to bet on, a bet amount $B_{i}, 0 \leq B_{i} \leq$ $C_{i-1}$, and a bet sign $b_{i} \in\{-1,+1\}$. The computation is legal so long as $x_{i}$ does not belong to the set $\left\{x_{1}, \ldots, x_{i-1}\right\}$ of strings queried in earlier stages. $G$ ends stage $i$ by entering a special query state. For a given oracle language $A$, if $x_{i} \in A$ and $b_{i}=+1$, or if $x_{i} \notin A$ and $b_{i}=-1$, then the new capital is given by $C_{i}:=C_{i-1}+B_{i}$, else by $C_{i}:=C_{i-1}-B_{i}$. We charge $M$ for the time required to write the numerator and denominator of the new capital $C_{i}$ down. The query and bet tapes are blanked, and $G$ proceeds to stage $i+1$.

In this paper, we lose no generality by not allowing $G$ to "crash" or to loop without writing a next bet and query. Note that every oracle set $A$ determines a unique infinite computation of $G$, which we denote by $G^{A}$. This includes a unique infinite sequence $x_{1}, x_{2}, \ldots$ of query strings, and a unique sequence $C_{0}, C_{1}, C_{2}, \ldots$ telling how the gambler fares against $A$.

Definition 3.2. A betting machine $G$ runs in time $t(n)$ if for all oracles $A$, every query of length $n$ made by $G^{A}$ is made in the first $t(n)$ steps of the computation.

Definition 3.3. A betting game $G$ succeeds on a language $A$, written $A \in$ $S^{\infty}[G]$, if the sequence of values $C_{i}$ in the computation $G^{A}$ is unbounded. If $A \in$ $S^{\infty}[G]$, then we also say $G$ covers $A$.

Our main motivating example where one may wish not to bet in lexicographic order, or according to any fixed ordering of strings, is deferred to section 6 . There we will construct an E-betting game that succeeds on the class of $\leq_{T}^{p}$-autoreducible languages, which is not known to have Lutz measure zero in E or EXP.

We now want to argue that the more liberal requirement of being covered by a time $t(n)$ betting game still defines a smallness concept for subclasses of DTIME[t $n$ )] in the intuitive sense Lutz established for his measure-zero notion. The following result is a good beginning.

Theorem 3.4. For every time-t $(n)$ betting game $G$, we can construct a language in DTIME $[t(n)]$ that is not covered by $G$.

Proof. Let $Q$ be a nonoracle Turing machine that runs as follows on any input $x$. The machine $Q$ simulates up to $t(|x|)$ steps of the single computation of $G$ on empty input. Whenever $G$ bets on and queries a string $y, Q$ gives the answer that causes $G$ to lose money, rejecting in the case of a zero bet. If and when $G$ queries $x, Q$ does likewise. If $t(|x|)$ steps go by without $x$ being queried, then $Q$ rejects $x$.

The important point is that $Q$ 's answer to a query $y \neq x$ is the same as the answer when $Q$ is run on input $y$. The condition that $G$ cannot query a string $x$ of length $n$ after $t(n)$ steps have elapsed ensures that the decision made by $Q$ when $x$ is not queried does not affect anything else. Hence $Q$ defines a language on which $G$ never does better than its initial capital $C_{0}$ and so does not succeed.

In particular, the class $E$ cannot be covered by an E-betting game, nor EXP by an EXP-betting game. Put another way, the "measure conservation axiom" [Lutz92] of Lutz's measure carries over to betting games.

To really satisfy the intuition of "small," however, it should hold that the union of two small classes is small. (Moreover, "easy" countable unions of small classes should be small, as in [Lutz92].) Our lack of meeting this "finite union axiom" will later be excused insofar as it has the nonrelativizing consequence BPP $\neq$ EXP. Theorem 3.4 is still good enough for the "measure-like" results in this paper.

We note also that several robustness properties of Lutz's measure treated in section 2 carry over to betting games. This is because we can apply the underlying transformations to the capital function $c_{G}$ of $G$, which is defined as follows.

Definition 3.5. Let $G$ be a betting game, and let $i \geq 0$ be an integer.
(a) A play $\alpha$ of length $i$ is a sequence of $i$-many oracle answers. Note that $\alpha$ determines the first i-many stages of $G$, together with the query and bet for the next stage.
(b) $c_{G}(\alpha)$ is the capital $C_{i}$ that $G$ has at the end of the play $\alpha$ (before the next query).
Note that the function $c_{G}$ is a martingale over plays $\alpha$. The proof of Lemma 2.3 works for $c_{G}$. We obtain the following lemma.

Lemma 3.6 ("slow-but-sure winnings" lemma for betting games). Let $G$ be a betting game that runs in time $t(n)$. Then we can construct a betting game $G^{\prime}$ that runs in time $\left(2^{n} t(n)\right)^{O(1)}$ such that $S^{\infty}[G] \subseteq S^{\infty}\left[G^{\prime}\right], G^{\prime}$ always makes the same queries in the same order as $G$, and

$$
\begin{align*}
& \forall \beta, \forall \gamma: c_{G^{\prime}}(\beta \gamma)>c_{G^{\prime}}(\beta)-2 c_{G}(\lambda)  \tag{5}\\
& \forall \alpha: c_{G^{\prime}}(\alpha)<2(|\alpha|+1) c_{G}(\lambda) \tag{6}
\end{align*}
$$

Proof. The proof of Lemma 2.3 carries over.
To begin comparing betting games and martingales, we note first that the latter can be considered a direct special case of betting games. Say a betting game $G$ is lex-limited if for all oracles $A$, the sequence $x_{1}, x_{2}, x_{3} \ldots$ of queries made by $G^{A}$ is in lexicographic order. (It need not equal the lexicographic enumeration $s_{1}, s_{2}, s_{3}, \ldots$ of $\Sigma^{*}$.)

Theorem 3.7. Let $\mathcal{T}(n)$ be a collection of time bounds that is closed under squaring and under multiplication by $2^{n}$, such as $2^{O(n)}$ or $2^{n^{O(1)}}$. Then a class $\mathcal{C}$ has time- $\mathcal{T}(n)$ measure zero iff $\mathcal{C}$ is covered by a time- $\mathcal{T}(n)$ lex-limited betting game.

Proof. From a martingale $d$ to a betting game $G$, each stage $i$ of $G^{A}$ bets on $s_{i}$ an amount $B_{i}$ with sign $b_{i} \in\{-1,+1\}$ given by $b_{i} B_{i}=d(w 1)-d(w)$, where $w$ is the first $i-1$ bits of the characteristic sequence of $A$. This takes $O\left(2^{n}\right)$ evaluations of $d$ to run $G$ up through queries of length $n$, hence the hypothesis on the time bounds $\mathcal{T}(n)$. In the other direction, when $G$ is lex-limited, one can simulate $G$ on a finite initial segment $w$ of its oracle up to a stage where all queries have been answered by $w$ and $G$ will make no further queries in the domain of $w$. One can then define $d(w)$ to be the capital entering this stage. That this is a martingale and fulfills the success and run-time requirements is left to the reader.

Hence in particular for measure on E and EXP, martingales are equivalent to betting games constrained to bet in lexicographic order. Now we will see how we can transform a general betting game into an equivalent martingale.
4. From betting games to martingales. This section associates to every betting game $G$ a martingale $d_{G}$ such that $S^{\infty}[G] \subseteq S^{\infty}\left[d_{G}\right]$, and begins examining the complexity of $d_{G}$. Before defining $d_{G}$, however, we pause to discuss some tricky subtleties of betting games and their computations.

Given a finite initial segment $w$ of an oracle language $A$, one can define the partial computation $G^{w}$ of the betting game up to the stage $i$ at which it first makes a query $x_{i}$ that is not in the domain of $w$. Define $d(w)$ to be the capital $C_{i-1}$ that $G$ had entering this stage. It is tempting to think that $d$ is a martingale and succeeds on all $A$ for which $G$ succeeds-but neither statement is true in general. The most important reason is that $d$ may fail to be a martingale.

To see this, suppose $x_{i}$ itself is the lexicographically least string not in the domain of $w$. That is, $x_{i}$ is indexed by the bit $b$ of $w b$, and $w 1 \sqsubseteq A$ iff $x_{i} \in A$. It is possible that $G^{A}$ makes a small (or even zero) bet on $x_{i}$, and then goes back to make more bets in the domain of $w$, winning lots of money on them. The definitions of both $d(w 0)$ and $d(w 1)$ will then reflect these added winnings, and both values will be greater than $d(w)$. For example, suppose $G^{A}$ first puts a zero bet on $x_{i}=s_{j}$, then bets all of its money on $x_{i+1}=s_{j-1}$ not being in $A$, and then proceeds with $x_{i+2}=s_{j+1}$. If $w\left(s_{j-1}\right)=0$, then $d(w 0)=d(w 1)=2 d(w)$.

Put another way, a finite initial segment $w$ may carry much more "winnings potential" than the above definition of $d(w)$ reflects. To capture this potential, one needs to consider potential plays of the betting game outside the domain of $w$. Happily, one can bound the length of the considered plays via the running time function $t$ of $G$. Let $n$ be the maximum length of a string indexed by $w$; i.e., $n=\left\lfloor\log _{2}(|w|)\right\rfloor$. Then after $t(n)$ steps, $G$ cannot query any more strings in the domain of $w$, so $w$ 's potential is exhausted. We will define $d_{G}(w)$ as an average value of those plays that can happen, given the query answers fixed by $w$. We use the following definitions and notation.

Definition 4.1. For any $t(n)$ time-bounded betting game $G$ and string $w \in \Sigma^{*}$, define the following.
(a) A play $\alpha$ is $t$-maximal if $G$ completes the first $|\alpha|$ stages, but not the query and bet of the next stage, within $t$ steps.
(b) A play $\alpha$ is $G$-consistent with $w$, written $\alpha \sim_{G} w$, if for all stages $j$ such that the queried string $x_{j}$ is in the domain of $w, \alpha_{j}=w\left(x_{j}\right)$. That is, $\alpha$ is a play that could possibly happen given the information in $w$. Also let $m(\alpha, w)$ stand for the number of such stages $j$ whose query is answered by $w$.
(c) Finally, put $d_{G}(\lambda)=c_{G}(\lambda)$, and for nonempty $w$, with $n=\left\lfloor\log _{2}(|w|)\right\rfloor$ as above, let

$$
\begin{equation*}
d_{G}(w)=\sum_{\alpha t(n)-\text { maximal }, \alpha \sim_{G} w} c_{G}(\alpha) 2^{m(\alpha, w)-|\alpha|} . \tag{7}
\end{equation*}
$$

The weight $2^{m(\alpha, w)-|\alpha|}$ in (7) has the following meaning. Suppose we extend the simulation of $G^{w}$ by flipping a coin for every query outside the domain of $w$ for exactly $i$ stages. Then the number of coin-flips in the resulting play $\alpha$ of length $i$ is $i-m(\alpha, w)$, so $2^{m(\alpha, w)-i}$ is its probability. Thus $d_{G}(w)$ returns the suitably-weighted average of $t(n)$-step computations of $G$ with $w$ fixed. The interested reader may verify that this is the same as averaging $d(w v)$ over all $v$ of length $2^{t(n)}$ (or any fixed longer length), where $d$ is the nonmartingale defined at the beginning of this section.

Lemma 4.2. The function $d_{G}(w)$ is a martingale.
Proof. First we argue that

$$
\begin{equation*}
d_{G}(w)=\sum_{\left|\alpha^{\prime}\right|=t(n), \alpha^{\prime} \sim{ }_{G} w} c_{G}\left(\alpha^{\prime}\right) 2^{m\left(\alpha^{\prime}, w\right)-t(n)} \tag{8}
\end{equation*}
$$

Observe that when $\alpha^{\prime}=\alpha \beta$ and $\alpha$ is $t(n)$-maximal, $\alpha \sim_{G} w \Longleftrightarrow \alpha^{\prime} \sim_{G} w$. This is because none of the queries answered by $\beta$ can be in the domain of $w$, else the definition of $G$ running in time $t(n)$ would be violated. Likewise if $\alpha \sim_{G} w$, then $m\left(\alpha^{\prime}, w\right)=$ $m(\alpha, w)$. Finally, since $c_{G}$ is a martingale, $c_{G}(\alpha)=\sum_{|\beta|=t(n)-|\alpha|} c_{G}(\alpha \beta) 2^{|\alpha|-t(n)}$. These facts combine to show the equality of (7) and (8).

By the same argument, the right-hand side of (8) is unchanged on replacing " $t(n)$ " by any $t^{\prime}>t(n)$.

Now consider $w$ such that $|w|+1$ is not a power of 2 . Then the " $n$ " for $w 0$ and $w 1$ is the same as the " $n$ " for $d_{G}(w)$. Let $P_{0}$ stand for the set of $\alpha$ of length $t(n)$ that are $G$-consistent with $w 0$ but not with $w 1, P_{1}$ for those that are $G$-consistent with $w 1$ but not $w 0$, and $P$ for those that are consistent with both. Then the set $\left\{\alpha:|\alpha|=t(n), \alpha \sim_{G} w\right\}$ equals the disjoint union of $P, P_{0}$, and $P_{1}$. Furthermore, for $\alpha \in P_{0}$ we have $m(\alpha, w 0)=m(\alpha, w)+1$, and similarly for $P_{1}$, while for $\alpha \in P$ we have $m(\alpha, w 0)=m(\alpha, w 1)=m(\alpha, w)$. Hence $d_{G}(w 0)+d_{G}(w 1)$ is given by

$$
\begin{gathered}
\sum_{\alpha \in P \cup P_{0}} c_{G}(\alpha) 2^{m(\alpha, w 0)-t(n)}+\sum_{\alpha \in P \cup P_{1}} c_{G}(\alpha) 2^{m(\alpha, w 1)-t(n)} \\
=\sum_{\alpha \in P_{0}} c_{G}(\alpha) 2^{m(\alpha, w 0)-t(n)}+\sum_{\alpha \in P_{1}} c_{G}(\alpha) 2^{m(\alpha, w 1)-t(n)}+2 \sum_{\alpha \in P} c_{G}(\alpha) 2^{m(\alpha, w)-t(n)} \\
=2 \sum_{\alpha \in P_{0}} c_{G}(\alpha) 2^{m(\alpha, w)-t(n)}+2 \sum_{\alpha \in P_{1}} c_{G}(\alpha) 2^{m(\alpha, w)-t(n)}+2 \sum_{\alpha \in P} c_{G}(\alpha) 2^{m(\alpha, w)-t(n)} \\
=2 d_{G}(w) .
\end{gathered}
$$

Finally, if $|w|+1$ is a power of 2 , then $d_{G}(w 0)$ and $d_{G}(w 1)$ use $t^{\prime}:=t(n+1)$ for their length of $\alpha$. However, by the first part of this proof, we can replace $t(n)$ by $t^{\prime}$ in the definition of $d_{G}(w)$ without changing its value, and then the second part goes through the same way for $t^{\prime}$. Hence $d_{G}$ is a martingale.

It is still the case, however, that $d_{G}$ may not succeed on the languages on which the betting game $G$ succeeds. To ensure this, we first use Lemma 3.6 to place betting games $G$ into a suitable "normal form" satisfying the sure-winnings condition (5).

Lemma 4.3. If $G$ is a betting game satisfying the sure-winnings condition (5), then $S^{\infty}[G] \subseteq S^{\infty}\left[d_{G}\right]$.

Proof. First, let $A \in S^{\infty}[G]$, and fix $k>0$. Find a finite initial segment $w \sqsubseteq A$ long enough to answer every query made in a play $\alpha$ of $G$ such that $\alpha \sim_{G} w$ and $c_{G}(\alpha) \geq k+2$ and long enough to make $t(n)$ in the definition of $d_{G}(w)$ (see (7)) greater than $|\alpha|$. Then every $\alpha^{\prime}$ of length $t(n)$ such that $\alpha^{\prime} \sim_{G} w$ has the form $\alpha^{\prime}=\alpha \beta$. The sure-winnings condition (5) implies that the right-hand side of (7) defining $d_{G}(w)$ is an average over terms that all have size at least $k$. Hence $d_{G}(w) \geq k$. Letting $k$ grow to infinity gives $A \in S^{\infty}\left[d_{G}\right]$.

Now we turn our attention to the complexity of $d_{G}$. If $G$ is a time- $t(n)$ betting game, it is clear that $d_{G}$ can be computed deterministically in $O(t(n))$ space, because we need only cycle through all $\alpha$ of length $t(n)$, and all the items in (7) are computable in space $O(t(n))$. In particular, every E-betting game can be simulated by a martingale whose values are computable in deterministic space $2^{O(n)}$ (even counting the output against the space bound), and every EXP-betting game can be simulated by a martingale similarly computed in space $2^{n^{O(1)}}$. However, we show in the next section that one can estimate $d_{G}(w)$ well without having to cycle through all the $\alpha$, using a pseudorandom generator to "sample" only a very small fraction of them.
5. Sampling results. First we determine the accuracy to which we need to estimate the values $d(w)$ of a hard-to-compute martingale. We state a stronger version of the result than we need in this section. In the next section, we will apply it to martingales whose "activity" is restricted to subsets $J$ of $\{0,1\}^{*}$ in the following sense: for all strings $x \notin J$, and all $w$ such that $s_{|w|+1}=x, d(w 0)=d(w 1)=d(w)$. Intuitively, a martingale $d$ is inactive on a string $x$ if there is no possible "past history" $w$ that causes a nonzero bet to be made on $x$. For short we say that such a $d$ is inactive outside $J$. Recall that $N=\Theta\left(2^{n}\right)$.

Lemma 5.1. Let $d$ be a martingale that is inactive outside $J \subseteq\{0,1\}^{*}$, and let $[\epsilon(i)]_{i=0}^{\infty}$ be a nonnegative sequence such that $\sum_{s_{i} \in J} \epsilon(i)$ converges to a number $K$. Suppose we can compute in time $t(n)$ a function $g(w)$ such that $|g(w)-d(w)| \leq \epsilon(N)$ for all $w$ of length $N$. Then there is a martingale $d^{\prime}$ computable in time $\left(2^{n} t(n)\right)^{O(1)}$ such that for all $w,\left|d^{\prime}(w)-d(w)\right| \leq 4 K+2 \epsilon(0)$.

In this section, we will apply Lemma 5.1 with $J=\{0,1\}^{*}$ and $\epsilon(N)=1 / N^{2}=$ $1 / 2^{2 n}$. In section 6.3 we will apply Lemma 5.1 in cases where $J$ is finite.

Proof. First note that for any $w$ (with $N=|w|$ ),

$$
\begin{align*}
\left|g(w)-\frac{g(w 0)+g(w 1)}{2}\right| & \leq|g(w)-d(w)|+\left|\frac{d(w 0)-g(w 0)}{2}\right|+\left|\frac{d(w 1)-g(w 1)}{2}\right| \\
& \leq \epsilon(N)+\epsilon(N+1) \tag{9}
\end{align*}
$$

In case $J=\{0,1\}^{*}$, we inductively define

$$
\left\{\begin{aligned}
d^{\prime}(\lambda) & =g(\lambda)+2 K+\epsilon(0) \\
d^{\prime}(w b) & =d^{\prime}(w)+g(w b)-\frac{g(w 0)+g(w 1)}{2}
\end{aligned}\right.
$$

Note that $d^{\prime}$ satisfies the average law (1), and that we can compute $d^{\prime}(w)$ in time $O\left(2^{n} t(n)\right)$.

By induction on $|w|$, we can show using the estimate provided by (9) that

$$
g(w)+\epsilon(N)+2 \sum_{i=N+1}^{\infty} \epsilon(i) \leq d^{\prime}(w) \leq g(w)+2 \sum_{i=0}^{N-1} \epsilon(i)+\epsilon(N)+2 K
$$

It follows that

$$
\begin{aligned}
d^{\prime}(w) & \geq g(w)+\epsilon(N) \\
& =d(w)+(g(w)-d(w))+\epsilon(N) \geq d(w)
\end{aligned}
$$

and that

$$
d^{\prime}(w)=d(w)+(g(w)-d(w))+\left(d^{\prime}(w)-g(w)\right)
$$

$$
\begin{aligned}
& \leq d(w)+\epsilon(N)+2 \sum_{i=0}^{N-1} \epsilon(i)+\epsilon(N)+2 K \\
& \leq d(w)+4 K+2 \epsilon(0)
\end{aligned}
$$

This establishes the lemma in case $J=\{0,1\}^{*}$. The generalization to other subsets $J$ of $\{0,1\}^{*}$ is left to the reader.

Next, we specify precisely which function $f_{G}$ we will sample in order to estimate $d_{G}$ and how we will do it.

Let $G$ be a $t(n)$ time-bounded betting game. Consider a prefix $w$, and let $n$ denote the largest length of a string in the domain of $w$. With any string $\rho$ of length $t(n)$, we can associate a unique "play of the game" $G$ defined by using $w$ to answer queries in the domain of $w$ and the successive bits of $\rho$ to answer queries outside it. We can stop this play after $t(n)$ steps-so that the stopped play is a $t(n)$-maximal $\alpha$-and then define $f_{G}(w, \rho)$ to be the capital $c_{G}(\alpha)$. Note that we can compute $f_{G}(w, \rho)$ in linear time, i.e., in time $O(|w|+t(n))$. The proportion of strings $\rho$ of length $t(n)$ that map to the same play $\alpha$ is exactly the weight $2^{m(\alpha, w)-|\alpha|}$ in (7) for $d_{G}(w)$. Letting $E$ stand for mathematical expectation, this gives us

$$
d_{G}(w)=E_{|\rho|=t(n)}\left[f_{G}(w, \rho)\right] .
$$

To obtain good and efficient approximations to the right-hand side, we employ pseudorandom generators. The following supplies all relevant definitional background.

Definition 5.2 (see [NiWi94]).
(a) The hardness $H_{A}(n)$ of a set $A$ at length $n$ is the largest integer $s$ such that for any circuit $C$ of size at most $s$ with $n$ inputs,

$$
\left|\operatorname{Pr}_{x}[C(x)=A(x)]-\frac{1}{2}\right| \leq \frac{1}{s}
$$

where $x$ is uniformly distributed over $\Sigma^{n}$.
(b) A pseudorandom generator is a function $D$ that, for each $n$, maps $\Sigma^{n}$ into $\Sigma^{r(n)}$, where $r(n) \geq n+1$. The function $r$ is called the stretching of $D$.
(c) The security $S_{D}(n)$ of $D$ at length $n$ is the largest integer such that, for any circuit $C$ of size at most $s$ with $r(n)$ inputs,

$$
\left|\operatorname{Pr}_{x}[C(x)=1]-\operatorname{Pr}_{y}[C(D(y))=1]\right| \leq \frac{1}{s}
$$

where $x$ is uniformly distributed over $\Sigma^{r(n)}$ and $y$ over $\Sigma^{n}$.
We will use pseudorandom generators with the following characteristics:
(1) an E-computable pseudorandom generator $D_{1}$ that stretches seeds superpolynomially and has super-polynomial security at infinitely many lengths;
(2) an EXP-computable pseudorandom generator $D_{2}$ of security $2^{n^{\Omega(1)}}$; and
(3) an E-computable pseudorandom generator $D_{3}$ of security $2^{\Omega(n)}$.
$D_{1}$ will be applied in the next section; in this section we will use $D_{2}$ and $D_{3}$. None of these generators is known to exist unconditionally. However, a highly plausible hypothesis suffices for the weakest generator $D_{1}$, as follows simply by combining the work of [BFNW93] and [NiWi94] with some padding.

ThEOREM 5.3. If MA $\neq \mathrm{EXP}$, then there is an E-computable pseudorandom generator $D_{1}$ with stretching $n^{\Theta(\log n)}$ such that for any integer $k$, there are infinitely many $n$ with $S_{D_{1}}(n)>n^{k}$.

Proof. From the proof of Lemma 4.1 of [BFNW93], it follows that if MA $\neq$ EXP, then there is a set $A \in \operatorname{EXP}$ such that for any integer $j$, there are infinitely many $m$ such that $H_{A}(m)>m^{j}$. From the proof of the main Theorem 1 in [NiWi94], it follows that for any set $A \in E \mathrm{EXP}$, there is an EXP-computable pseudorandom generator $D$ with stretching $n^{\Theta(\log n)}$ such that $S_{D}(n)=\Omega\left(H_{A}(\sqrt{n}) / n\right)$. Say that $D$ is computable in time $2^{n^{c}}$ for some integer constant $c>0$. For any $k>0$, the infinitely many $m$ promised above with $j=2(c k+1)$ yield infinitely many $n$ of the form $m^{2 / c}$ such that $S_{D}\left(n^{1 / c}\right)>n^{k}$. Defining $D_{1}(x)=D\left(x^{\prime}\right)$, where $x^{\prime}$ denotes the prefix of $x$ of length $|x|^{1 / c}$, yields the required pseudorandom generator.

Exponential-time computable pseudorandom generators with exponential security have the interesting property that we can blow up the stretching exponentially without significantly reducing the security. As with Theorem 5.3, credit for this observation should be distributed among the references cited in the proof.

Theorem 5.4.
(a) Given an EXP-computable pseudorandom generator $D_{0}$ of security $2^{n^{5(1)}}$, we can construct an EXP-computable pseudorandom generator $D_{2}$ of security $2^{n^{s(1)}}$ and stretching $2^{n^{[2(1)}}$.
(b) Given an E-computable pseudorandom generator $D_{0}$ of security $2^{\Omega(n)}$, we can construct an E-computable pseudorandom generator $D_{3}$ of security $2^{\Omega(n)}$ and stretching $2^{\Omega(n)}$.
Proof. For (a), Nisan and Wigderson [NiWi94] showed that the existence of an Ecomputable pseudorandom generator with stretching $n+1$ (a "quick extender" in their terminology) with security $2^{n^{\Omega(1)}}$ is equivalent to the existence of an E-computable pseudorandom generator with stretching and security $2^{n^{\Omega(1)}}$. See statements (3) and (4) of their main theorem (Theorem 1) instantiated with $s(\ell)=2^{\ell}$. As used in [BFNW93], their main result carries through if we replace "E-computable" by "EXPcomputable" in both statements, owing to padding. Since the existence of $D_{0}$ implies the existence of an EXP-computable extender with security $2^{n^{\Omega(1)}}$, the existence of $D_{2}$ follows.

For (b), first define $D^{\prime}(x)$ to be the first $|x|+1$ bits of $D_{0}(x)$. Then $D^{\prime}$ is an extender with security $2^{\Omega(n)}$, and this implies that the range of $D^{\prime}$ is a language in E requiring circuits of size $2^{\Omega(n)}$. Impagliazzo and Wigderson, in their proof of Theorem 2 in [ImWi97], showed how to transform such a language into a language $A \in E$ such that $H_{A}(n)=2^{\Omega(n)}$. Using this $A$ in part (3) of Theorem 2 of [NiWi94] yields an E-computable pseudorandom generator $D_{3}$ of security and stretching $2^{\Omega(n)}$. (It is also possible to argue that the range of $D^{\prime}$ is sufficiently hard to employ the technique of [ NiWi 94 ], without going through [ ImWi 97$]$.)

Pseudorandom generators of security $2^{n^{\Omega(1)}}$ (even polynomial-time computable ones) are fairly widely believed to exist (see [BlMi84, RaRu97, Bon99]), and while those of security $2^{\Omega(n)}$ are more controversial even for EXP-computability, their existence was made more plausible by the result of [ImWi97] used in the proof of (b) above. Polynomial-time computable pseudorandom generators of security $2^{\Omega(n)}$ exist relative to a random oracle [Zim95, Imp99pc], and E-computable ones also exist if $\mathrm{P}=\mathrm{NP}$. (The latter observation follows by combining the techniques of Kannan [Kan82] with padding and the above-mentioned result of [ $\operatorname{ImWi} 97$ ]; it is noted by the second author as "Corollary 2.2.19" in his dissertation [Mel99].)

The following general result shows how pseudorandom generators can be used to approximate averages. It provides the accuracy and time bounds needed for applying Lemma 5.1 to get the desired martingale.

THEOREM 5.5. Let $D$ be a pseudorandom generator computable in time $\delta(n)$ and with stretching $r(n)$. Let $f: \Sigma^{*} \times \Sigma^{*} \rightarrow(-\infty, \infty)$ be a function that is computed in linear time on a Turing machine, and let $s, R, m: \mathbf{N} \rightarrow \mathbf{N}$ be fully time-constructible functions such that $s(N) \geq N$ and the following relations hold for any integer $N \geq 0$, $w \in \Sigma^{N}$, and $\rho \in \Sigma^{s(N)}$ :

$$
\begin{align*}
|f(w, \rho)| & \leq R(N) \\
r(m(N)) & \geq s(N) \\
S_{D}(m(N)) & \geq(s(N)+R(N))^{6} . \tag{10}
\end{align*}
$$

Then we can approximate

$$
\begin{equation*}
h(w)=E_{|\rho|=s(N)}[f(w, \rho)] \tag{11}
\end{equation*}
$$

to within $N^{-2}$ in time $O\left(2^{m(N)} \cdot(s(N)+R(N))^{4} \cdot \delta(m(N))\right)$.
Proof. For any $N \geq 0$, let $\mathcal{I}_{N}$ be a partition of the interval $[-R(N), R(N)]$ into subintervals of length $\frac{1}{2 N^{2}}$. Note that $\left|\mathcal{I}_{N}\right|=4 N^{2} R(N)$. Define for any $I \in \mathcal{I}_{N}$ and any string $w$ of length $N$

$$
\pi(I, w)=\operatorname{Pr}_{|\rho|=s(N)}[f(w, \rho) \in I]
$$

The predicate in [..] can be computed by circuits of size $O(s(N) \log s(N))$, using the $t$-to- $O(t \log t)$ Turing-machine-time-to-circuit-size construction of Pippenger and Fischer [PiFi79]. Since $S_{D}(m(N))=\omega(s(N) \log s(N))$, it follows that

$$
\tilde{\pi}(I, w)=\operatorname{Pr}_{|\sigma|=m(N)}[f(w, D(\sigma)[1 \ldots s(N)]) \in I]
$$

approximates $\pi(I, w)$ to within an additive error of $\left(S_{D}(m(N))\right)^{-1}$, and we can compute it in time $O\left(2^{m(N)} \cdot s(N) \cdot \delta(m(N))\right)$. We define the approximation $\tilde{h}(w)$ for $h(w)$ as

$$
\tilde{h}(w)=\sum_{I \in \mathcal{I}_{N}} \tilde{\pi}(I, w) \min (I)
$$

Since we can write $h(w)$ as

$$
h(w)=\sum_{I \in \mathcal{I}_{N}} \pi(I, w) E_{|\rho|=s(N)}[f(w, \rho) \mid f(w, \rho) \in I]
$$

we can bound the approximation error as follows:

$$
\begin{aligned}
& |h(w)-\tilde{h}(w)| \\
& \leq \sum_{I \in \mathcal{I}_{N}} \pi(I, w)\left|E_{|\rho|=s(N)}[f(w, \rho) \mid f(w, \rho) \in I]-\min (I)\right| \\
& \quad+\sum_{I \in \mathcal{I}_{N}}|\pi(I, w)-\tilde{\pi}(I, w)| \min (I) \\
& \leq \max _{I \in \mathcal{I}_{N}}(|I|)+\left|\mathcal{I}_{N}\right| \cdot\left(S_{D}(m(N))\right)^{-1} \cdot R(N) \\
& \leq \frac{1}{2 N^{2}}+4 N^{2} \cdot R^{2}(N) \cdot\left(S_{D}(m(N))\right)^{-1} \leq \frac{1}{N^{2}}
\end{aligned}
$$

Computing $\tilde{h}(w)$ requires $\left|\mathcal{I}_{N}\right|=4 N^{2} R(N)$ evaluations of $\tilde{\pi}$, which results in the claimed upper bound for the time complexity of $\tilde{h}$.

Now we would like to apply Theorem 5.5 to approximate $h=d_{G}$ given by (7) to within $N^{-2}$, by setting $f=f_{G}$ and $s(N)=t(\log N)$. However, for a general betting game $G$ running in time $t(n)$, we can only guarantee an upper bound of $R(N)=2^{t(\log N)} \cdot c_{G}(\lambda)$ on $|f(w, \rho)|$. Since $S_{D}$ can be at most exponential, condition (10) would force $m(N)$ to be $\Omega(t(\log N))$. In that case, Theorem 5.5 can only yield an approximation computable in time $2^{O(t(\log N))}$. However, we can assume without loss of generality that $G$ satisfies the slow-winnings condition (6) of Lemma 3.6, in which case an upper bound of $R(N) \in O(N)$ holds. Then the term $s(N)$ in the right-hand side of (10) dominates, provided $t(n)=2^{\Omega(n)}$.

Taking everything together, we obtain the following result about transforming Eand EXP-betting games into equivalent E-, respectively, EXP-martingales.

Theorem 5.6. If there is a pseudorandom generator computable in E with security $2^{\Omega(n)}$, then for every E-betting game $G$, there exists an E-martingale $d$ such that $S^{\infty}[G] \subseteq S^{\infty}[d]$. If there is a pseudorandom generator computable in EXP with security $2^{n^{s(1)}}$, then for every EXP-betting game $G$, there exists an EXP-martingale d such that $S^{\infty}[G] \subseteq S^{\infty}[d]$.

Proof. By Lemma 3.6, we can assume that $c_{G}$ satisfies both the sure-winnings condition (5) as well as the slow-winnings condition (6). Because of Lemmas 4.3 and 5.1 (since the series $\sum_{i=1}^{\infty} \frac{1}{i^{2}}$ converges), it suffices to approximate the function $d_{G}(w)$ given by (7) to within $N^{-2}$ in time $2^{O(n)}$, respectively, $2^{n^{O(1)}}$, where $N=|w|$ and $n=\log N$.

Under the given hypothesis about the existence of an E-computable pseudorandom generator $D_{0}$, we can take $D$ to be the pseudorandom generator $D_{3}$ provided by Theorem $5.4(\mathrm{~b})$. Thus we meet the conditions for applying Theorem 5.5 to $h=d_{G}$ with $s(N)=N^{O(1)}, R(N)=O(N)$, and $m(N)=O(\log N)$, and we obtain the approximation of $d_{G}$ that we need. In the case of an EXP-betting game $G$, to obtain an EXP-martingale we can take $D$ to be the pseudorandom generator $D_{2}$ of weaker security guarantee $2^{n^{\Omega(1)}}$ provided by Theorem 5.4(a). Then we meet the requirements of Theorem 5.5 with $s(N)=2^{(\log N)^{O(1)}}, R(N)=O(N)$, and $m(N)=(\log N)^{O(1)}$.
6. Autoreducible sets. An oracle Turing machine $M$ is said to autoreduce a language $A$ if $L\left(M^{A}\right)=A$, and for all strings $x, M^{A}$ on input $x$ does not query $x$. That is, one can learn the membership of $x$ by querying strings other than $x$ itself. If $M$ runs in polynomial time, then $A$ is P -autoreducible-we also write $\leq_{T}^{p}$-autoreducible. If $M$ is also nonadaptive, then $A$ is $\leq_{t t}^{p}$-autoreducible.

One can always code $M$ so that for all oracles, it never queries its own inputthen we call $M$ an autoreduction. Hence we can define an effective enumeration $\left[M_{i}\right]_{i=1}^{\infty}$ of polynomial-time autoreductions, such that a language $A$ is autoreducible iff there exists an $i$ such that $L\left(M_{i}^{A}\right)=A$. (For a technical aside: the same $M_{i}$ may autoreduce different languages $A$, and some $M_{i}$ may autoreduce no languages at all.) The same goes for $\leq_{t t}^{p}$-autoreductions.

Autoreducible sets were brought to the polynomial-time context by Ambos-Spies [Amb84]. Their importance was further argued by Buhrman, Fortnow, Van Melkebeek, and Torenvliet [BFvMT98], who showed that all $\leq_{T}^{p}$-complete sets for EXP are $\leq_{T}^{p}$-autoreducible (while some complete sets for other classes are not). Here we demonstrate that autoreducible sets are important for testing the power of resourcebounded measure.
6.1. Adaptively autoreducible sets. As stated in the introduction, if the $\leq_{T^{-}}^{p}$ autoreducible sets in EXP (or sufficiently the $\leq_{T}^{p}$-complete sets for EXP) are covered by an EXP-martingale, then EXP $\neq B P P$, a nonrelativizing consequence. However, it is easy to cover them by an E-betting game. Indeed, the betting game uses its adaptive freedom only to "look ahead" at the membership of lexicographically greater strings, betting nothing on them.

THEOREM 6.1. There is an E-betting game $G$ that covers all $\leq_{T}^{p}$-autoreducible languages.

Proof. Let $M_{1}, M_{2}, \ldots$ be an enumeration of $\leq_{T}^{p}$-autoreductions such that each $M_{i}$ runs in time $n^{i}+i$ on inputs of length $n$. Our betting game $G$ regards its capital as composed of infinitely many "shares" $c_{i}$, one for each $M_{i}$. Initially, $c_{i}=1 / 2^{i}$. Letting $\langle\cdot, \cdot\rangle$ be a standard pairing function, inductively define $n_{0}=0$ and $n_{\langle i, j\rangle+1}=$ $\left(n_{\langle i, j\rangle}\right)^{i}+i$.

During a stage $s=\langle i, j\rangle, G$ simulates $M_{i}$ on input $0^{n_{s-1}}$. Whenever $M_{i}$ makes a query of length less than $n_{s-1}, G$ looks up the answer from its table of past queries. Whenever $M_{i}$ makes a query of length $n_{s-1}$ or more, $G$ places a bet of zero on that string and makes the same query. Then $G$ bets all of the share $c_{i}$ on $0^{n_{s-1}}$ according to the answer of the simulation of $M_{i}$. Finally, $G$ "cleans up" by putting zero bets on all strings with length in $\left[n_{s-1}, n_{s}\right.$ ) that were not queries in the previous steps.

If $M_{i}$ autoreduces $A$, then share $c_{i}$ doubles in value at each stage $\langle i, j\rangle$ and makes the total capital grow to infinity. And $G$ runs in time $2^{O(n)}$-indeed, only the "cleanup" phase needs this much time.

Corollary 6.2. Each of the following statements implies BPP $\neq$ EXP.

1. The class of $\leq_{T}^{p}$-autoreducible sets has E-measure zero.
2. The class of $\leq_{T}^{P}$-complete sets for EXP has E-measure zero.
3. E-betting games and E-martingales are equivalent.
4. E-betting games have the finite union property.

The same holds if we replace E by EXP in these statements.
Proof. Let $\mathcal{C}$ stand for the class of languages that are not $\leq_{T}^{p}$-hard for BPP. Allender and Strauss [AISt94] showed that $\mathcal{C}$ has E-measure zero, so trivially it is also covered by an E-betting game. Now let $\mathcal{D}$ stand for the class of $\leq_{T}^{p}$-complete sets for EXP. By Theorem 6.1 and the result of [BFvMT98] cited above, $\mathcal{D}$ is covered by an E-betting game.

If EXP $=\mathrm{BPP}$, the union $\mathcal{C} \cup \mathcal{D}$ contains all of EXP, and

- if $\mathcal{D}$ would have E-measure zero, so would $\mathcal{C} \cup \mathcal{D}$ and hence EXP, contradicting the measure conservation property of Lutz measure;
- if E-betting games would have the finite-union property, then $\mathcal{C} \cup \mathcal{D}$ and EXP would be covered by an E-betting game, contradicting Theorem 3.4.
Since statement 1 implies statement 2 , and statement 3 implies statement 4 , then these observations suffice to establish the corollary for E. The proof for EXP is similar.

Since there is an oracle $A$ giving $\operatorname{EXP}^{A}=\operatorname{BPP}^{A}[\mathrm{Hel86}]$, this shows that relativizable techniques cannot establish the equivalence of E-martingales and E-betting games, nor of EXP-martingales and EXP-betting games. They cannot refute it either, since there are oracles relative to which strong pseudorandom generators exist-all "random" oracles, in fact [Zim95].
6.2. Nonadaptively autoreducible sets. It is tempting to think that the nonadaptively P-autoreducible sets should have E-measure zero, or at least EXPmeasure zero, insofar as betting games are the adaptive cousins of martingales. How-
ever, it is not just adaptiveness but also the freedom to bet out of the fixed lexicographic order that adds power to betting games. If one carries out the proof of Theorem 6.1 to cover the class of $\leq_{t t}^{p}$-autoreducible sets, using an enumeration $\left[M_{i}\right]$ of $\leq_{t t}^{p}$-autoreductions, one obtains a nonadaptive E-betting game (defined formally below) that (independent of its oracle) bets on all strings in an order given by a single permutation of $\Sigma^{*}$. The permutation itself is E-computable. It might seem that an E-martingale should be able to "untwist" the permutation and succeed on all these sets. However, our next results, which strengthen the above corollary, close the same "nonrelativizing" door on proving this with current techniques.

THEOREM 6.3. For any $k \geq 1$, the $\leq_{t t}^{p}$-complete languages for $\Delta_{k}^{p}$ are $\leq_{t t}^{p}$ autoreducible.

Here is the proof idea, which follows techniques of [BFvMT98] for the theorem that all EXP-complete sets are $\leq_{T}^{p}$-autoreducible. Call a closed propositional formula that has at most $k$ blocks of like quantifiers (i.e., at most $k-1$ quantifier alternations) a "QBF $k$ formula," and let $T Q B F_{k}$ stand for the set of true QBF formulas. Let $A$ be $\mathrm{a} \leq_{t t}^{p}$-complete set for $\Delta_{k+1}^{p}=\mathrm{P}^{\Sigma_{k}^{p}}$. Since $T Q B F_{k}$ is $\Sigma_{k}^{p}$-hard, there is a deterministic polynomial-time oracle Turing machine $M$ that accepts $A$ with oracle $T Q B F_{k}$. Let $q(x, i)$ stand for the $i$ th oracle query made by $M$ on input $x$. Whether $q(x, i)$ belongs to $T Q B F_{k}$ forms a $\Delta_{k+1}^{p}$-question, so we can $\leq_{t t}^{p}$-reduce it to $A$. It is possible that this latter reduction will include $x$ itself among its queries. Let $b_{i}^{+}$denote the answer it gives to the question provided that any query to $x$ is answered "yes," and similarly define $b_{i}^{-}$in case $x$ is answered "no."

If $b_{i}^{+}=b_{i}^{-}$, which holds in particular if $x$ is not queried, then we know the correct answer $b_{i}$ to the $i$ th query. If this situation occurs for all queries, we are finished: We just have to run $M$ on input $x$ using the $b_{i}$ 's as answers to the oracle queries. The $b_{i}$ 's themselves are obtained without submitting the (possibly adaptive) queries made by $M$, but rather by applying the latter $\leq_{t t}^{p}$-reduction to $A$ to the pair $\langle x, i\rangle$, and without submitting any query on $x$ itself. Hence this process satisfies the requirements of a $\leq_{t t}^{p}$-autoreduction of $A$ for the particular input $x$.

Now suppose that $b_{i}^{+} \neq b_{i}^{-}$for some $i$, and let $i$ be minimal. Then we will have two players play the $k$-round game underlying the $\mathrm{QBF}_{k}$-formula that constitutes the $i$ th oracle query. One player claims that $b_{i}^{+}$is the correct value for $b_{i}$, which is equivalent to claiming that $x \in A$, while his opponent claims that $b_{i}^{-}$is correct and that $x \notin A$. Write $\chi_{A}(x)=1$ if $x \in A$, and $\chi_{A}(x)=0$ if $x \notin A$. The players' strategies will consist of computing the game history so far, determining their optimal next move, $\leq_{t t}^{p}$-reducing this computation to $A$, and finally producing the result of this reduction under their respective assumption about $\chi_{A}(x)$. This approach will allow us to recover the game history in polynomial time with nonadaptive queries to $A$ different from $x$. Moreover, it will guarantee that the player making the correct assumption about $\chi_{A}(x)$ plays optimally. Since this player is also the one claiming the correct value for $b_{i}$, he will win the game. So, we output the winner's value for $b_{i}$.

It remains to show that we can compute the above strategies in deterministic polynomial time with a $\Sigma_{k}^{p}$ oracle, i.e., in $\mathrm{FP}^{\Sigma_{k}^{p}}$. It seems crucial that the number $k$ of alternations be constant here.

Proof of Theorem 6.3. Let $A$ be a $\leq_{t t}^{p}$-complete set for $\Delta_{k+1}^{p}$ accepted by the polynomial-time oracle Turing machine $M$ with oracle $T Q B F_{k}$. Let $q(x, i)$ denote the $i$ th oracle query of $M^{T Q B F_{k}}$ on input $x$. Then $q(x, i)$ can be written in the form $\left(\exists y_{1}\right)\left(\forall y_{2}\right) \ldots\left(Q_{k} y_{k}\right) \phi_{x, i}\left(y_{1}, y_{2}, \ldots, y_{k}\right)$, where $y_{1}, \ldots, y_{k}$ stand for the vectors of variables quantified in each block, or in the opposite form beginning with the
block $\left(\forall y_{1}\right)$. By reasonable abuse of notation, we also let $y_{r}$ stand for a string of $0-1$ assignments to the variables in the $r$ th block. Without loss of generality, we may suppose every oracle query made by $M$ has this form where each $y_{j}$ is a string of length $|x|^{c}$, and $M$ makes exactly $|x|^{c}$ queries, taking the constant $c$ from the polynomial time bound on $M$. Note that the function $q$ belongs to $\mathrm{FP}^{\Sigma_{k}^{p}}$. Hence the language

$$
L_{0}=\left\{\langle x, y\rangle: q(x, i) \in T Q B F_{k}\right\}
$$

belongs to $\Delta_{k+1}^{p}$. Since $A$ is $\leq_{t t}^{p}$-complete for $\Delta_{k+1}^{p}$, there is a polynomial-time nonadaptive oracle Turing machine $N_{0}$ that accepts $L_{0}$ with oracle $A$. Now define $b_{i}^{+}(x)=$ $N_{0}^{A \cup\{x\}}(\langle x, i\rangle)$ and $b_{i}^{-}(x)=N_{0}^{A \backslash\{x\}}(\langle x, i\rangle)$. We define languages $L_{1}, L_{2}, \ldots, L_{k} \in$ $\Delta_{k+1}^{p}$ and $\leq_{t t}^{p}$-reductions $N_{1}, N_{2}, \ldots, N_{k}$ inductively as follows.

Let $1 \leq \ell \leq k$. The set $L_{\ell}$ consists of all pairs $\langle x, j\rangle$ with $1 \leq j \leq|x|^{c}$, such that there is a smallest $i, 1 \leq i \leq|x|^{c}$, for which $b_{i}^{+}(x) \neq b_{i}^{-}(x)$, and the following condition holds. For $1 \leq r \leq \ell-1$, let the $s$ th bit of $y_{r}$ equal $N_{r}^{A \cup\{x\}}(\langle x, s\rangle)$ if $r \equiv b_{i}^{+}(x) \bmod 2$, and ${N_{r}^{A}}^{A} \backslash x\}(\langle x, s\rangle)$ otherwise. We put $\langle x, j\rangle$ into $L_{\ell}$ iff there is a lexicographically least $y_{\ell}$ such that

$$
\chi\left[\left(Q_{\ell+1} y_{\ell+1}\right)\left(Q_{\ell+2} y_{\ell+2}\right) \ldots\left(Q_{k} y_{k}\right) \phi_{x, i}\left(y_{1}, y_{2}, \ldots, y_{k}\right)\right] \equiv \ell \bmod 2
$$

and the $j$ th bit of $y_{\ell}$ is set to 1 . The form of this definition shows that $L_{\ell}$ belongs to $\Delta_{k+1}^{p}$. Hence we can take $N_{\ell}$ to be a polynomial-time nonadaptive oracle Turing machine that accepts $L_{\ell}$ with oracle $A$.

Now, we construct a $\leq_{t t}^{p}$-autoreduction for $A$. On input $x$, we compute $b_{i}^{+}(x)$ and $b_{i}^{-}(x)$ for $1 \leq i \leq|x|^{c}$, as well as $y_{r}^{(b)}$ for $b \in\{0,1\}$ and $1 \leq r \leq|x|^{c}$. The latter quantity $y_{r}^{(b)}$ is defined as follows: for $1 \leq s \leq|x|^{c}$, the $s$ th bit of $y_{r}^{(b)}$ equals $N_{r}^{A \cup\{x\}}(\langle x, s\rangle)$ if $r \equiv b \bmod 2$, and $N_{r}^{A \backslash\{x\}}(\langle x, s\rangle)$ otherwise. Note that we can compute all these values in polynomial time by making nonadaptive queries to $A$, none of which equals $x$.

If $b_{i}^{+}(x)=b_{i}^{-}(x)$ for every $1 \leq i \leq|x|^{c}$, we run $M$ on input $x$ using $b_{i}^{+}(x)=b_{i}^{-}(x)$ as the answer to the $i$ th oracle query. Since it always holds that at least one of $b_{i}^{+}(x)$ and $b_{i}^{-}(x)$ equals the correct oracle answer $b_{i}(x)$, we faithfully simulate $M$ on input $x$ and hence compute $\chi_{A}(x)$ correctly.

Otherwise, let $i$ be the first index for which $b_{i}^{+}(x) \neq b_{i}^{-}(x)$. Since $b_{j}(x)=b_{j}^{+}(x)=$ $b_{j}^{-}(x)$ for $j<i$, we can determine $q(x, i)$ by simulating $M$ on input $x$ until it asks the $i$ th query. We then output 1 if

$$
b_{i}^{+}(x)=\phi_{x, i}\left(y_{1}^{\left(b_{i}^{+}(x)\right)}, y_{2}^{\left(b_{i}^{+}(x)\right)}, \ldots, y_{k}^{\left(b_{i}^{+}(x)\right)}\right)
$$

and output 0 otherwise. We claim that this gives the correct answer to whether $x \in A$.
In order to prove the claim, consider the game history $y_{1}^{\left(b_{i}^{+}(x)\right)}, y_{2}^{\left(b_{i}^{+}(x)\right)}, \ldots$, $y_{k}^{\left(b_{i}^{+}(x)\right)}$. The player claiming the correct value for $b_{i}(x)$ gets to play the rounds that allow him to win the game no matter what his opponent does. Since this player is also the one making the correct assumption about $\chi_{A}(x)$, an inductive argument shows that he plays optimally: At his stages $\ell$, the string $y_{\ell}$ in the above construction of $L_{\ell}$ exists, and he plays it. The key for the induction is that at later stages $\ell^{\prime}>\ell$, the value of $y_{\ell}$ at stage $\ell^{\prime}$ remains the same as what it was at stage $\ell$. Thus the player with the correct assumption about $\chi_{A}(x)$ wins the game-that is,
$\phi_{x, i}\left(y_{1}^{\left(b_{i}^{+}(x)\right)}, y_{2}^{\left(b_{i}^{+}(x)\right)}, \ldots, y_{k}^{\left(b_{i}^{+}(x)\right)}\right)$ equals his guess for $b_{i}(x)$ (and not the other player's guess).

In order to formalize the strengthening of Corollary 6.2 that results from Theorem 6.3 , we call a betting game $G$ nonadaptive if the infinite sequence $x_{1}, x_{2}, x_{3}, \ldots$ of queries $G^{A}$ makes is the same for all oracles $A$. If $G$ runs in $2^{O(n)}$ time, and this sequence hits all strings in $\Sigma^{*}$, then the permutation $\pi$ of the standard ordering $s_{1}, s_{2}, s_{3}, \ldots$ defined by $\pi\left(s_{i}\right)=x_{i}$ is both computable and invertible in $2^{O(n)}$ time. It is computable in this amount of time because in order to hit all strings, $G$ must bet on all strings in $\{0,1\}^{n}$ within the first $2^{O(n)}$ steps. Hence its $i$ th bet must be made in a number of steps that is singly-exponential in the length of $s_{i}$. And to compute $\pi^{-1}\left(x_{i}\right), G$ need only be run for $2^{O\left(\left|x_{i}\right|\right)}$ steps, since it cannot query $x_{i}$ after this time. Since $\pi$ and its inverse are both E-computable, $\pi$ is a reasonable candidate to replace lexicographic ordering in the definition of E-martingales, and likewise for EXP-martingales. We say a class $\mathcal{C}$ has $\pi$-E-measure zero if $\mathcal{C}$ can be covered by an E-martingale that interprets its input as a characteristic string in the order given by $\pi$.

ThEOREM 6.4. The class of $\leq_{t t}^{p}$-autoreducible languages can be covered by a nonadaptive E-betting game. Hence there is an E-computable and invertible permutation $\pi$ of $\Sigma^{*}$ such that this class has $\pi$-E-measure zero.

Proof. With reference to the proof of Theorem 6.1 , we can let $M_{1}, M_{2}, \ldots$ be an enumeration of $\leq_{t t}^{p}$-autoreductions such that each $M_{i}$ runs in time $n^{i}+i$. The machine $G$ in that proof automatically becomes nonadaptive, and since it queries all strings, it defines a permutation $\pi$ of $\Sigma^{*}$ as above with the required properties. $\quad$.

Corollary 6.5. Each of the following statements implies BPP $\neq \mathrm{EXP}$, as do the statements obtained on replacing "E" by "EXP."

1. The class of $\leq_{t t}^{p}$-autoreducible sets has E-measure zero.
2. The class of $\leq_{t t}^{p}$-complete sets for EXP has E-measure zero.
3. Nonadaptive E-betting games and E-martingales are equivalent.
4. If two classes can be covered by nonadaptive E-betting games, then their union can be covered by an E-betting game.
5. For all classes $\mathcal{C}$ and all E-computable and invertible orderings $\pi$, if $\mathcal{C}$ has $\pi$-E-measure zero, then $\mathcal{C}$ has E -measure zero.
Proof. It suffices to make the following two observations to argue that the proof of Corollary 6.2 carries over to the truth-table cases.

- The construction of Allender and Strauss [AlSt94] actually shows that the class of sets that are not $\leq_{t t}^{p}$-hard for BPP has E-measure zero.
- If EXP $=\mathrm{BPP}$, Theorem 6.3 implies that all $\leq_{t t}^{p}$-complete sets for EXP are $\leq_{t t}^{p}$-autoreducible, because BPP $\subseteq \Sigma_{2}^{\mathrm{p}} \subseteq \Delta_{3}^{\mathrm{p}} \subseteq$ EXP.
Theorem 6.4 and the finite-unions property of Lutz's measures on E and EXP do the rest.

The last point of Corollary 6.5 asserts that Lutz's definition of measure on $E$ is invariant under all E-computable and invertible permutations. These permutations include flip from the introduction and (crucially) $\pi$ from Theorem 6.4. Hence this robustness assertion for Lutz's measure implies BPP $\neq$ EXP. Our "betting-game measure" (both adaptive and nonadaptive) does enjoy this permutation invariance, but asserting the finite-unions property for it also implies BPP $\neq$ EXP. The rest of this paper explores conditions under which Lutz's martingales can cover classes of autoreducible sets, thus attempting to narrow the gap between them and betting games.
6.3. Covering autoreducible sets by martingales. This puts the spotlight on the question: Under what hypotheses can we show that the $\leq_{t t}^{p}$-autoreducible sets have E-measure zero? Any such hypothesis must be strong enough to imply EXP $\neq \mathrm{BPP}$, but we hope to find hypotheses weaker than assuming the equivalence of (E- or EXP-) betting games and martingales, or assuming the finite-union property for betting games. Do we need strong pseudorandom generators to cover the $\leq_{t t^{-}}^{p}$ autoreducible sets? How close can we come to covering the $\leq_{T}^{p}$-autoreducible sets by an E-martingale?

Our final results show that the hypothesis MA $\neq$ EXP suffices. This assumption is only known to yield pseudorandom generators of super-polynomial security (at infinitely many lengths) rather than exponential security (at almost all lengths). Recall that MA contains both BPP and NP; in fact it is sandwiched between NP ${ }^{B P P}$ and $B P P^{N P}$.

THEOREM 6.6. If $\mathrm{MA} \neq \mathrm{EXP}$, then the class of $\leq_{t t}^{p}$-autoreducible sets has E measure zero.

We actually obtain a stronger conclusion.
ThEOREM 6.7. If MA $\neq \mathrm{EXP}$, then the class of languages $A$ autoreducible by polynomial-time oracle Turing machines that always make their queries in lexicographic order has E-measure zero.

To better convey the essential sampling idea, we prove the weaker Theorem 6.6 before the stronger Theorem 6.7. The extra wrinkle in the latter theorem is to use the pseudorandom generator twice, both to construct the set of "critical strings" to bet on and to compute the martingale.

Proof of Theorem 6.6. Let $\left[M_{i}\right]_{i=1}^{\infty}$ enumerate the $\leq_{t t}^{p}$-autoreductions, with each $M_{i}$ running in time $n^{i}$. Divide the initial capital into shares $s_{i, m}$ for $i, m \geq 1$, with each $s_{i, m}$ valued initially at $\left(1 / m^{2}\right)\left(1 / 2^{i}\right)$. For each share $s_{i, m}$, we will describe a martingale that is active only on a finite number of strings $x$. The martingale will be active only if $i \leq m / 2\left\lceil\log _{2} m\right\rceil$ and $m \leq|x| \leq m^{i}$, and further only if $x$ belongs to a set $J=J_{i, m}$ constructed below. Hence the martingale will be inactive outside $J$, and we will be able to apply Lemma 5.1. We will arrange that whenever $M_{i}$ autoreduces $A$, there are infinitely many $m$ such that share $s_{i, m}$ attains a value above 1 (in fact, close to $m$ ) along $A$. Hence the martingale defined by all the shares succeeds on $A$. We will also ensure that each active share's bets on strings of length $n$ are computable in time $2^{a n}$, where the constant $a$ is independent of $i$. This is enough to make the whole martingale E-computable and complete the proof.

To describe the betting strategy for $s_{i, m}$, first construct a set $I=I_{i, m}$ starting with $I=\left\{0^{m}\right\}$ and iterating as follows: Let $y$ be the lexicographically least string of length $m$ that does not appear among queries made by $M_{i}$ on inputs $x \in I$. Then add $y$ to $I$. Do this until $I$ has $3\left\lceil\log _{2} m\right\rceil$ strings in it. This is possible because the bound $3\left\lceil\log _{2} m\right\rceil m^{i}$ on the number of queries $M_{i}$ could possibly make on inputs in $I$ is less than $2^{m}$. Moreover, $2^{m}$ bounds the time needed to construct $I$. Thus we have arranged that

$$
\begin{equation*}
\text { for all } x, y \in I \text { with } x<y, M_{i}(x) \text { does not query } y \text {. } \tag{12}
\end{equation*}
$$

Now let $J$ stand for $I$ together with all the queries $M_{i}$ makes on inputs in $I$. Adapting ideas from Definition 4.1 to this context, let us define a finite Boolean function $\beta$ : $J \rightarrow\{0,1\}$ to be consistent with $M_{i}$ on $I$, written $\beta \sim_{I} M_{i}$, if for all $x \in I, M_{i}$ run on input $x$ with oracle answers given by $\beta$ agrees with the value $\beta(x)$. Given a characteristic prefix $w$, also write $\beta \sim w$ if $\beta(x)$ and $w(x)$ agree on all $x$ in $J$ and
the domain of $w$. Since $I$ and $J$ depend only on $i$ and $m$, we obtain a "probability density" function for each share $s_{i, m}$ via

$$
\begin{equation*}
\pi_{i, m}(w)=\operatorname{Pr}_{\beta \sim w}\left[\beta \sim_{I} M_{i}\right] . \tag{13}
\end{equation*}
$$

The martingale $d_{i, m}$ standardly associated to this density (as in [Lutz92]) is definable inductively by $d_{i, m}(\lambda)=1$ and

$$
\begin{equation*}
d_{i, m}(w 1)=d_{i, m}(w) \frac{\pi_{i, m}(w 1)}{\pi_{i, m}(w)}, \quad \quad d_{i, m}(w 0)=d_{i, m}(w) \frac{\pi_{i, m}(w 0)}{\pi_{i, m}(w)} \tag{14}
\end{equation*}
$$

(In case $\pi_{i, m}=0$, we already have $d_{i, m}(w)=0$, and so both $d_{i, m}(w 1)$ and $d_{i, m}(w 0)$ are set to 0 .)

Note that the values $\pi_{i, m}(w b)$ for $b=0,1$ can only differ from $\pi_{i, m}(w)$ if the string $x$ indexed by $b$ belongs to $J$, i.e., $d_{i, m}$ is inactive outside $J$.

Claim 6.8. If $M_{i}$ autoreduces $A$, then for all sufficiently large $m$, if share $s_{i, m}$ could play the strategy $d_{i, m}$, then on $A$ its value would rise to (at least) $m / 2^{i}$. That is, $s_{i, m}$ would multiply its initial value by (at least) $\mathrm{m}^{3}$.

To see this, first note that for any $w \sqsubseteq A$ long enough to contain $J$ in its domain, $\pi_{i, m}(w)=1$. We want to show that for any $v$ short enough to have domain disjoint from $I, \pi_{i, m}(v)=1 / 2^{|I|}$. To do this, consider any fixed $0-1$ assignment $\beta_{0}$ to strings in $J \backslash I$ that agrees with $v$. This assignment determines the computation of $M_{i}$ on the lexicographically first string $x \in I$, using $\beta_{0}$ to answer queries, and hence forces the value of $\beta(x)$ in order to maintain consistency on $I$. This in turn forces the value $\beta\left(x^{\prime}\right)$ on the next string $x^{\prime}$ in $I$, and so on. Hence only one out of $2^{|I|}$ possible completions of $\beta_{0}$ to $\beta$ is consistent with $M_{i}$ on $I$. Thus $\pi_{i, m}(v)=1 / 2^{|I|}$. Since $d_{i, m}(w)=d_{i, m}(v) \cdot\left(\pi_{i, m}(w) / \pi_{i, m}(v)\right)$ by (14), and $2^{|I|}=2^{\left.3 \mid \log _{2} m\right]} \geq m^{3}$, Claim 6.8 is proved.

The main obstacle now is that $\pi_{i, m}$ in (13), and hence $d_{i, m}(w)$, may not be computable in time $2^{a n}$ with $a$ independent of $i$. The number of assignments $\beta$ to count is on the order of $2^{|J|} \approx 2^{m^{i}} \approx 2^{n^{i}}$. Here is where we use the E-computable pseudorandom generator $D_{1}$, with super-polynomial stretching and with super-polynomial security at infinitely many lengths, obtained via Theorem 5.3 from the hypothesis MA $\neq$ EXP. For all $i$ and sufficiently large $m, D_{1}$ stretches a seed $s$ of length $m$ into at least $3\left\lceil\log _{2} m\right\rceil m^{i}$ bits, which are enough to define an assignment $\beta_{s}$ to $J$ (agreeing with any given $w$ ). We estimate $\pi_{i, m}(w)$ by

$$
\begin{equation*}
\hat{\pi}_{i, m}(w)=\operatorname{Pr}_{|s|=m}\left[\beta_{s} \sim_{I} M_{i}\right] . \tag{15}
\end{equation*}
$$

Take $\epsilon=1 / m^{i+4}$. By Theorem 5.3 there are infinitely many "good" $m$ such that $S_{D_{1}}(m)>m^{i+4}$.

Claim 6.9. For all large enough good $m$, every estimate $\hat{\pi}_{i, m}(w)$ gives $\mid \hat{\pi}_{i, m}(w)-$ $\pi_{i, m}(w) \mid \leq \epsilon$.

Suppose not. First note that (13) and (15) do not depend on all of $w$, just on the up-to- $3\left[\log _{2} m\right\rceil m^{i}<m^{i+1}$ bits in $w$ that index strings in $J$, and these can be hardwired into circuits. The tests $\left[\beta \sim_{I} M_{i}\right]$ can also be done by circuits of size $o\left(m^{i+1}\right)$, because a Turing machine computation of time $r$ can be simulated by circuits of size $O(r \log r)$ [PiFi79]. Hence we get circuits of size less than $S_{D_{1}}(m)$ achieving a discrepancy greater than $1 / S_{D_{1}}(m)$, which is a contradiction. This proves Claim 6.9.

Finally, observe that the proof of Claim 6.8 gives us not only $d_{i, m}(w) \geq \pi_{i, m}(w)$. $m^{3}$, but also $d_{i, m}(w)=\Theta\left(\pi_{i, m}(w) \cdot m^{3}\right)$, when $w \sqsubseteq A$. For $w \sqsubseteq A$ and good $m$, we
thus obtain estimates $g(w)$ for $d_{i, m}(w)$ within error bounds $\epsilon^{\prime}=\Theta(\epsilon)=\Theta\left(1 / m^{i+1}\right)$. Now applying Lemma 5.1 for this $g(w)$ and $J=J_{i, m}$ yields a martingale $d_{i, m}^{\prime}(w)$ computable in time $2^{a n}$, where the constant $a$ is independent of $i$. This $d_{i, m}^{\prime}(w)$ is the martingale computed by the actions of share $s_{i, m}$. Since $K=\sum_{s_{i} \in J} \epsilon^{\prime}=|J| \epsilon^{\prime} \leq$ $(1 / m) \cdot 3\left\lceil\log _{2} m\right\rceil=o(1)$, we actually obtain $\left|d_{i, m}^{\prime}(w)-d_{i, m}(w)\right|=o(1)$, which is stronger than what we needed to conclude that share $s_{i, m}$ returns enough profit. This completes the proof of Theorem 6.6.

To prove Theorem 6.7, we need to construct sets $I=I_{i, m}$ with properties similar to (12), in the case where $M_{i}$ is no longer a $\leq_{t t}^{p}$-autoreduction but makes its queries in lexicographic order. To carry out the construction of $I$, we use the pseudorandom generator $D_{1}$ a second time and actually need only that $M_{i}$ on input $0^{m}$ makes all queries of length $<m$ before making any query of length $\geq m$. To play the modified strategy for share $s_{i, m}$, however, appears to require that all queries observe lexicographic order.

Proof of Theorem 6.7. Recall that the hypothesis EXP $\neq$ MA yields a pseudorandom generator $D_{1}$ computable in time $2^{O(m)}$ and stretching $m$ bits to $r(m)$ bits such that for all $i$, all sufficiently large $m$ give $r(m)>m^{i}$, and infinitely many $m$ give hardness $S_{D_{1}}(m)>m^{i}$. Let $\left[M_{i}\right]_{i=1}^{\infty}$ be a standard enumeration of $\leq_{T}^{p}$-autoreductions that are constrained to make their queries in lexicographic order, with each $M_{i}$ running in time $O\left(n^{i}\right)$. We need to define strategies for "shares" $s_{i, m}$ such that whenever $M_{i}$ autoreduces $A$, there are infinitely many $m$ such that share $s_{i, m}$ grows its initial capital from $1 / m^{2} 2^{i}$ to $1 / 2^{i}$ or more. The strategy for $s_{i, m}$ must still be computable in time $2^{a m}$ where $a$ is independent of $i$.

To compute the strategy for $s_{i, m}$, we note first that $s_{i, m}$ can be left inactive on strings of length $<m$. The overall running time allowance $2^{O(m)}$ permits us to suppose that by the time $s_{i, m}$ becomes active and needs to be considered, the initial segment $w_{0}$ of $A$ (where $A$ is the language on which the share happens to be playing) that indexes strings of length up to $m-1$ is known. Hence we may regard $w_{0}$ as fixed. For any $\alpha \in\{0,1\}^{m^{2}}$ let $M_{i}^{\alpha}(x)$ stand for the computation in which $w_{0}$ is used to answer any queries of length $<m$ and $\alpha$ is used to answer all other queries. Because of the order in which $M_{i}$ makes its queries, those queries $y$ answered by $w_{0}$ are the same for all $\alpha$, so that those answers can be coded by a string $u_{0}$ of length at most $m^{i}$. Now for any string $y$ of length equal to $m$, define

$$
P(x, y)=\operatorname{Pr}_{\alpha}\left[M_{i}^{\alpha}(x) \text { queries } y\right]
$$

Note that given $u_{0}$ and $\alpha$, the test " $M_{i}^{\alpha}(x)$ queries $y$ " can be computed by circuits of size $O\left(m^{i+1}\right)$. Hence by using the pseudorandom generator $D_{1}$ at length $m$, we can compute uniformly in E an approximation $P_{1}(x, y)$ for $P(x, y)$ such that for infinitely many $m$, said to be "good" $m$, all pairs $x, y$ give $\left|P_{1}(x, y)-P(x, y)\right| \leq \epsilon_{m}$, where we choose $\epsilon_{m}=1 / m^{4}$.

Here is the algorithm for constructing $I=I_{i, m}$. Start with $I:=\emptyset$, and while $|I|<3 \log _{2} m$, do the following: Take the lexicographically least string $y \in \Sigma^{m} \backslash I$ such that for all $x \in I, P_{1}(x, y) \leq \epsilon_{m}$. The search for such a $y$ will succeed within $|I| \cdot m^{i+4}$ trials, since for any particular $x$, there are fewer than $m^{i+4}$ strings $y$ overall that will fail the test. (This is so even if $m$ is not good, because it only involves $P_{1}$, and because $P_{1}$ involves simulating $M_{i}^{D_{1}(s)}$ over all seeds s.) There is enough room to find such a $y$ provided $|I| m^{i+4} \leq 2^{m}$, which holds for all sufficiently large $m$. The whole construction of $I$ can be completed within time $2^{2 a m}$. It follows that for any sufficiently large good $m$ and $x, y \in I$ with $x<y, \operatorname{Pr}_{\alpha}\left[M_{i}^{\alpha}(x)\right.$ queries $\left.y\right]<2 \epsilon_{m}=$
$2 / m^{4}$.
At this point we would like to define $J$ to be " $I$ together with the set of strings queried by $M_{i}$ on inputs in $I "$ as before, but unlike the previous case where $M_{i}$ was nonadaptive, this is not a valid definition. We acknowledge the dependence of the strings queried by $M_{i}$ on the oracle $A$ by defining

$$
J_{A}:=I \cup\left\{y:(\exists x \in I) M_{i}^{A}(x) \text { queries } y\right\}
$$

Let $r=m^{i} \cdot\lceil 3 \log m\rceil$. Then $\left|J_{A}\right| \leq r$; that is, $J_{A}$ has the same size as $J$ in the previous proof. This latter definition will be OK because $M_{i}$ makes its queries in lexicographic order. Hence the share $s_{i, m}$, having already computed $I$ without any reference to $A$, can determine the strings in $J_{A}$ on which it should be active on the fly, in lexicographic order. Thus we can well-define a mapping $\beta$ from $\{0,1\}^{r}$ to $\{0,1\}$ so that for any $k \leq r, \beta(k)=1$ means that the query string $y$ that happens to be $k$ th in order in the on-the-fly construction of $J_{A}$ is answered "yes" by the oracle. Then we may write $J_{\beta}$ for $J_{A}$, and then write $\beta(y)=1$ in place of $\beta(k)=1$. Most important, given any $x \in I$, every such $\beta$ well-defines a computation $M_{i}^{\beta}(x)$. This entitles us to carry over the two "consistency" definitions from the proof of Theorem 6.6:

- $\beta \sim w$ if $\beta(y)=w(y)$ for all $y \in J_{\beta}$;
- $\beta \sim_{I} M_{i}$ if for all $x \in I, M_{i}^{\beta}(x)$ equals (i.e., "agrees with") $\beta(x)$.

Finally, we may apply the latter notion to initial subsets of $I$ and define for $1 \leq \ell \leq$ $3 \log m$ the predicate

$$
\begin{aligned}
R_{\ell}(\beta)= & \left(\beta \sim_{x_{1}, \ldots, x_{\ell}} M_{i}\right) \wedge \\
& (\forall j, k: 1 \leq j \leq k \leq \ell) M_{i}^{\beta}\left(x_{j}\right) \text { does not query } x_{k}
\end{aligned}
$$

Claim 6.10. For all $\ell, \operatorname{Pr}_{\beta}\left[R_{\ell}(\beta)\right] \leq 1 / 2^{\ell}$.
For the base case $\ell=1, \operatorname{Pr}_{\beta}\left[R_{1}(\beta)\right]=1 / 2$, because $M_{i}(x)$ does not query $x_{1}$, $M_{i}$ being an autoreduction, and because whether $\beta \sim_{x_{1}} M_{i}$ depends only on the bit of $\beta$ corresponding to $x_{1}$. Working by induction, suppose $\operatorname{Pr}_{\beta}\left[R_{\ell-1}(\beta)\right] \leq 1 / 2^{\ell-1}$. If $R_{\ell-1}(\beta)$ holds, then taking $\beta^{\prime}$ to be $\beta$ with the bit corresponding to $x_{\ell}$ flipped, $R_{\ell-1}\left(\beta^{\prime}\right)$ also holds. However, at most one of $R_{\ell}(\beta)$ and $R_{\ell}\left(\beta^{\prime}\right)$ holds, again because $M_{i}\left(x_{\ell}\right)$ does not query $x_{\ell}$. Hence $\operatorname{Pr}_{\beta}\left[R_{\ell}(\beta)\right] \leq(1 / 2) \operatorname{Pr}_{\beta}\left[R_{\ell-1}(\beta)\right]$, and this proves Claim 6.10. (It is possible that neither $R_{\ell}(\beta)$ nor $R_{\ell}\left(\beta^{\prime}\right)$ holds, as happens when $M_{i}^{\beta}\left(x_{j}\right)$ queries $x_{\ell}$ for some $j$, but this does not hurt the claim.)

Now we can rejoin the proof of Theorem 6.6 at (13), defining the probability density function $\pi_{i, m}(w)=\operatorname{Pr}_{\beta \sim w}\left[\beta \sim_{I} M_{i}\right]$. We get a martingale $d_{i, m}$ from $\pi_{i, m}$ as before, and this represents an "ideal" strategy for share $s_{i, m}$ to play. The statement corresponding to Claim 6.8 is the following.

Claim 6.11. If $M_{i}$ autoreduces $A$ and $m$ is good and sufficiently large, then the ideal strategy for share $s_{i, m}$ multiplies its value by at least $m^{3} / 2$ along $A$.

To see this, note that we constructed $I=\left\{x_{1}, \ldots, x_{3 \log m}\right\}$ above so that for all $j<k, \operatorname{Pr}_{\alpha}\left[M_{i}^{\alpha}\left(x_{j}\right)\right.$ queries $\left.x_{k}\right] \leq 2 / m^{4}$. It follows that

$$
\operatorname{Pr}\left[(\exists j, k: 1 \leq j \leq k \leq 3 \log m) M_{i}\left(x_{j}\right) \text { queries } x_{k}\right] \leq\binom{\lceil 3 \log m\rceil}{ 2} \cdot \frac{2}{m^{4}} \leq \frac{1}{m^{3}}
$$

provided $m \geq\lceil 3 \log m\rceil^{2}$. Hence, using Claim 6.10 with $\ell=3 \log m$, we get

$$
\operatorname{Pr}_{\beta}\left[\beta \sim_{I} M_{i}\right] \leq \frac{1}{2^{3 \log m}}+\frac{1}{m^{3}}=\frac{2}{m^{3}}
$$

Since the $\beta$ defined by $A$ satisfies $\beta \sim_{I} M_{i}$, it follows by the same reasoning as in Claim 6.8 that $d_{i, m}$ profits by at least a fraction of $m^{3} / 2$ along $A$. This proves Claim 6.11.

Finally, we (re)use the pseudorandom generator $D_{1}$ as before to expand a seed $s$ of length $m$ into a string $\beta_{s}$ of (at least) $r=3\left\lceil\log _{2} m\right\rceil m^{i}$ bits. Given any $w, \beta_{s}$ well-defines a $\beta$ and a set $J_{\beta}$ of size at most $r$ as constructed above by using $w$ to answer queries in the domain of $w$ and $\beta_{s}$ for everything else. We again obtain the estimate $\hat{\pi}_{i, m}(w)=\operatorname{Pr}_{|s|=m}\left[\beta_{s} \sim_{I} M_{i}\right]$ from (15), with the same time complexity as before. Now we repeat Claim 6.9 in this new context as follows.

Claim 6.12. For all large enough good $m$, every estimate $\hat{\pi}_{i, m}(w)$ gives $\mid \hat{\pi}_{i, m}(w)-$ $\pi_{i, m}(w) \mid \leq \epsilon$.

If not, then for some fixed $w$ the estimate fails. The final key point is that because $M_{i}$ always makes its queries in lexicographic order, the queries in the domain of $w$ that need to be covered are the same for every $\beta_{s}$. Hence the corresponding bits of $w$ can be hard-wired by circuitry of size at most $r$. The test $\left[\beta_{s} \sim_{I} M_{i}\right]$ can thus still be carried out by circuits of size less than $m^{i+1}$, and we reach the same contradiction of the hardness value $S_{D_{1}}$.

Finally, we want to apply Lemma 5.1 to replace $d_{i, m}(w)$ by a martingale $d_{i, m}^{\prime}(w)$ that yields virtually the same degree of success and is computable in time $2^{O(n)}$. Unlike the truth-table case, we cannot apply Lemma 5.1 verbatim because we no longer have a single small set $J$ that $d^{\prime}$ is active on. However, along any set $A$, the values $d_{i, m}^{\prime}(w)$ and $d_{i, m}^{\prime}(w b)(b=0$ or 1$)$ can differ only for cases where $b$ indexes a string in the small set $J$ corresponding to $A$, and the reader may check that the argument and bounds of Lemma 5.1 go through unscathed in this case. This finishes the proof of Theorem 6.7.
7. Conclusions. The initial impetus for this work was a simple question about measure: is the pseudorandomness of a characteristic sequence invariant under simple permutations such as that induced by fip in the introduction? The question for flip is tantalizingly still open. However, in section 6.2 we showed that establishing a "yes" answer for any permutation that intuitively should preserve the same complexitytheoretic degree of pseudorandomness, or even for a single specific such permutation as that in the simple proof of the nonadaptive version of Theorem 6.1, would have the major consequence that EXP $\neq \mathrm{BPP}$.

Our "betting games" in themselves are a natural extension of Lutz's measures for deterministic time classes. They preserve Lutz's original idea of "betting" as a means of "predicting" membership in a language, without being tied to a fixed order of instances that one tries to predict, or to a fixed order of how one goes about gathering information on the language. We have shown some aspects in which betting games are robust and well-behaved. We also contend that some current defects in the theory of betting games, notably the lack of a finite-unions theorem pending the status of pseudorandom generators, trade off with lacks in the resource-bounded measure theory, such as being tied to the lexicographic ordering of strings.

The main open problems in this paper are interesting in connection with recent work by Impagliazzo and Wigderson [ImWi98] on the BPP vs. EXP problem. First we remark that the main result of [ImWi98] implies that either BPP $=$ EXP or BPP has E-measure zero [Mel98]. Among the many measure statements in the last section that imply BPP $\neq$ EXP, the most constrained and easiest to attack seems to be item 4 in Corollary 6.5. Indeed, in the specific relevant case starting with the assumption $\mathrm{BPP}=\mathrm{EXP}$, one is given a nonadaptive E-betting game $G$ and an E-martingale
$d$, and to obtain the desired contradiction that proves $\mathrm{BPP} \neq \mathrm{EXP}$, one needs only construct an EXP-betting game $G^{\prime}$ that covers $S^{\infty}[G] \cup S^{\infty}[d]$. What we can obtain is a "randomized" betting game $G^{\prime \prime}$ that flips one coin at successive intervals of input lengths to decide whether to simulate $G$ or $d$ on that interval. (The intervals come from the proof of Theorem 6.4.) Any hypothesis that can derandomize this $G^{\prime \prime}$ implies BPP $\neq$ EXP. We do not know whether the weak hypotheses considered in [ $\operatorname{ImWi} 98$ ], some of them shown to follow from BPP $\neq$ EXP itself, are sufficient to do this.

Stepping back from trying to prove BPP $\neq$ EXP outright or trying to prove that these measure statements are equivalent to $\mathrm{BPP} \neq \mathrm{EXP}$, we also have the problem of narrowing the gap between BPP $\neq$ EXP and the sufficient condition EXP $\neq \mathrm{MA}$ used in our results. Moreover, does EXP $\neq$ MA suffice to make the $\leq_{T}^{p}$-autoreducible sets have E-measure zero? Does that suffice to simulate every betting game by a martingale of equivalent complexity? We also inquire whether there exist oracles relative to which EXP $=\mathrm{MA}$, but strong pseudorandom generators still exist. Our work seems to open many opportunities to tighten the connections among pseudorandom generators, the structure of classes within EXP, and resource-bounded measure.

The kind of statistical sampling used to obtain martingales in Theorems 5.5 and 5.6 was originally applied to construct martingales from "natural proofs" in [RSC95]. The derandomization technique from [BFNW93] based on EXP $\neq \mathrm{MA}$ that is used here is also applied in [BuMe98, KoLi98, LSW98]. "Probabilistic martingales" that can use this sampling to simulate betting games are formalized and studied in [ReSi98]. This paper also starts the task of determining how well the betting game and random-sampling ideas work for measures on classes below E. Even straightforward attempts to carry over Lutz's definitions to classes below E run into difficulties, as described in [May94t] and [AlSt94, AlSt95]. We look toward further applications of our ideas in lower-level complexity classes.

Acknowledgments. The authors especially thank Klaus Ambos-Spies, the late Ron Book, and Jack Lutz for organizing a special Schloss Dagstuhl workshop in July 1996, where preliminary versions of results and ideas in this paper were presented and extensively discussed. We thank the STACS ' 98 referees and the referees of this journal paper for helpful comments-one of the latter gave us many insightful notes that helped us steer away from errors and ambiguities in this final version.
