# HEAVY TRAFFIC ANALYSIS OF DYNAMIC CYCLIC POLICIES: A UNIFIED TREATMENT OF THE SINGLE MACHINE SCHEDULING PROBLEM 

David M. Markowitz<br>Logistics Management Institute<br>McLean. VA 22102<br>Lawrence M. Wein<br>Sloan School of Management. M.I.T.<br>Cambridge. MA 02139

#### Abstract

This paper examines how setups. due-dates and the mix of standardized and customized products affect the scheduling of a single machine operating in a dynamic and stochastic environment. We restrict ourselves to the class of dynamic cyclic policies. where the machine busy/idle policy and lot-sizing decisions are controlled in a dynamic fashion. but different products must be produced in a fixed sequence. As in earlier work. we conjecture that an averaging principle holds for this queueing system in the heavy traffic limit. and optimize over the class of dynamic cyclic policies. The results allow for a detailed discussion of the interactions between the due-date. setup and product mix facets of the problem.

and

2

This paper focuses on what we consider to be the three most important structural features of single machine scheduling problems. The first characteristic is the presence or absence of setup cosis and/or setup times when the machine switches from one type of product to another. Set up penalties force the scheduler to exploit the economies of scale. which leads to dynamic lot-sizing policies. The second factor is the presence or absence of adranced information regarding future demands. which gives rise to problems with and without due-dates. respectirely: This aspect of the problem essentially dictates the nature of the objective function: If adranced information is provided then the objective function is based on due-date considerations (e.g.. earliness and tardiness costs) and if no such information is available then the objective function is expressed in terms of system measures (e.g.. inventory costs. waiting time. throughput). The third characteristic is whet her products are customized or standardized. This feature is intimately related to the make-to-stock/make-to-order distinction: Customized products must be made-toorder whereas standardized products can (but do not need to) be made-to-stock.

The aim of this paper is to provide a unified (with respect to these three features) treatment of single machine scheduling in a dynamic and stochastic environment. More specificall: we consider a manufacturing srstem consisting of one machine that produces multiple trpes of goods. which we refer to as products. Each product can be either customized. which requires the request for an order before production can begin. or standardized. in which case they can be pre-stocked in a finished goods inventory: The machine is limited in capacity and can only produce one unit at a time. Whenever the machine switches from producing one product to another, a setup cost and/or setup time penalty is incurred. Orders arrive to the s!stem. each requesting a unit of the product at a specified due-date. A completed unit assigned to an order before the order`s due-date must be held and an earliness cost is incurred. Similarly: a tardiness fee is levied whenerer a completed unit is delivered to an order after its due-date. In addition. unassigned items held in finished goods inventory also incur a holding cost equal to the earliness fee of that (standardized) product. Interarrival times. service times. due-date lead times (an order's due-date minus its time of arrirall and setup times are random variables that can vary by product.

Figure 1: The eight subproblems under consideration.

In this setting. the machine at any point in time can idle. produce the product that it is currently set up for or initiate a setup for a different product. In other words. the scheduler makes three types of decisions in a dỵnamic fashion: Whether the machine should be busy or idle. how much to make of each product (i.e.. lot-sizing) and which product to produce next. In this paper. we restrict ourselves to drnamic crelic policies. which allows full discretion orer the first two decisions. but produces each product in a fixed cyclic sequence. We wish to optimize the queueing system with respect to long run expected average costs due to earliness. tardiness. holding and setups.

The Venn diagram in Figure 1 delineates the eight subproblems that are incorporated by our analysis. Athough only the general scheduling problem is considered throughout the body of the paper. $\$ 5$ is deroted to a discussion of each of the eight regions in the Tenn diagram. Since the existing literature has only examined specific regions of the Vemn diagram. we delay our literature revjew to this discussion.

This paper expands upon the methods of Markowitz. Reiman and Wein (1995) (abbreviated hereafter by MRIV). Which analyzes the stochastic economic lot scheduling
problem (depicted as subproblem $\frac{1}{4}$ in Figure 1). MRW applies Coffman. Puhalskii and Reiman's (1995a. 1995b) heary traffic areraging principle. which considers two sets of scalings: A fast one where time is sped up by a factor of $O(n)$ and a slow one where time is increased by a factor of $O(\sqrt{n})$ (where $n$ goes to infinity in the heary traffic limit). The fast scaling leads to a diffusion limit and the slow scaling leads to a fluid limit. The heary traffic averaging principle couples these two processes and makes this difficult scheduling problem amenable to analysis. As in MRW. we optimize the control problem. first in the fluid limit and then in the diffusion limit. The primary analytical contribution of this paper is to determine how due-dates affect the system beharior under the fluid limit. As in our previous applications of the heary traffic averaging principle (Reiman and Wein 1994. 1995. MRII and Reiman. Rubio and Wein 1995). we conjecture that this principle holds for the system under study: without providing a rigorous proof of convergence: see Reiman and Wein (1996) for a heuristic justification of this conjecture. Because a closed form solution has eluded us. we resort to developing a computational procedure for solving the control problem. However. to gain further insight, we analyze the special case where each product has a different deterministic (as opposed to random) due-date lead time: in this case. the results simplify considerably: Finally: a simulation study is performed to assess both the effectireness of our proposed policies and the accuracy of the hear: traffic approximation.

The scheduling problem is formulated in $\$ 1$ and heavy traffic preliminaries are introduced in $\S 2$. We perform a heary traffic analysis of the scheduling problem in $\S 3$ and work through the deterministic due-date lead time case in $\S$ t. Section 5 is devoted to a discussion of the subproblems outlined in the Venn diagram in Figure 1 and $\$ 6$ contains results of a computational study on due-date effects. Concluding remarks are offered in §7. Readers interested only in the qualitative insights derived from this work may omit §2. §3 and $\S 4$.

## 1. PROBLEMI FORMIULATION

I single machine produces . I different products. Without loss of generality: we assume that products $1.2 \ldots \ldots Y^{\text {are }}$ customized and $V^{2}+1 \ldots \ldots V^{\circ}+1^{\text {s }}=1$ are

standardized. Each product, has its own generally distributed service time with mean $\mu_{i}^{-1}$ and coefficient of variation $c_{1 s}$. Orders for goods arrive from an exogenous renewal demand process. For each product $i$. the interarrival times of orders are generally distributed with mean $\lambda_{1}^{-1}$ and coefficient of variation $c_{2 a}$. The arrival and service time processes for each product are assumed to be independent, although they need not be (see Reiman 1984 for the incorporation of correlated compound renewal processes). The utilization of product $i$ is $\rho_{2}=\lambda_{2} / \mu_{2}$ and the system utilization. or traffic intensity: is $\rho=\sum_{i=1}^{N} \rho_{i}$.

Orders arrive to the system with a specified due-date. The due-date lead time. which is the time interval between an order's arrival and its due-date. for product $i$ is a random variable with density $\tilde{f}_{2}(s)$. cumulative distribution function $\tilde{F}_{2}(s)$ and mean $\tilde{I}_{2}$. and is independent of the arrival and service processes. (For quantities that undergo scalings. a "tilde" denotes a lack of scaling. a "bar" denotes the fluid scaling. and no symbol above the quantity denotes the diffusion scaling.) We assume that the due-date lead time distribution has bounded support. and denote its minimum and maximum by $\tilde{a}_{\text {, }}$ and $\tilde{b}_{2}$. respectively: because due-date information typically reflects future demand. We further assume that $\hat{a}_{2} \geq 0$.

Orders for customized goods are immediately queued. The machine can only work on a customized product if an order is present. Once a customized order is serviced. the completed unit is either held until the order"s due-date or delivered immediately if the order is tardy: If the unit is held. the order incurs an earliness fee (holding cost) $\hat{h}_{2}$ per unit time until the due-date: if the order is past due. it incurs a tardiness fee (backorder cost) of $\hat{b}$, per unit time late. In anticipation of our subsequent analysis. We also express these cost parameters in terms of units of work: $h_{1}=\hat{h}_{1} \mu_{2}$ and $b_{1}=\hat{b}_{2} \mu_{2}$.

The flow of phrsical product and orders is more complex for standardized products. and we need to keep track of both orders and completed items. Completed items can be pre-stocked in the finished goods inventory. where each unit accrues holding costs at a rate of $\hat{h}$, per unit time. Orders for standardized products are queued upon arrival. and can be filled by an item either from the finished goods inventory or directly from the output of the machine. Once an item is assigned to an order. the ststem incurs either an earliness

fee $\hat{h}$, for each unit of time until the order's due-date or a tardiness fee of $\hat{b}$, per unit time tardy: Again. these costs have workload equivalents $h_{2}=\hat{h}_{1} \mu_{2}$ and $b_{2}=\hat{b}_{2} \mu_{2}$. Notice that we have made the natural assumption that the holding cost for an unallocated item in the finished goods inventory is identical to the earliness cost incurred when a completed item is allocated to a standardized order before its due-date (in the latter case. one can envision the item sitting on the shipping dock until the order's due-date). Hence. no benefit can be gained by assigning a completed item to a standardized order before its due-date: Delaying the allocation of completed items to orders results in more flexibility and a lower cost policy. Therefore without loss of generality: we only consider policies that incur no earliness fees for standardized products. and so standardized orders exit the system when completed items are assigned to them.

The scheduler can observe the system state at each point in time. To ease the notational burden. we only introduce notation in this section for those quantities that will be used in our subsequent heary traffic analysis. Let the slack of an order be its due-date minus the current time. Hence. an order's slack is identical to its due-date lead time when it arrives to the system. but the slack. which can be positive or negative. is a dynamic quantity that decreases at unit rate throughout the order's sojourn in the system. The system state includes the arrival time and the slack of each order in each product's queue. the number of items of each standardized product in finished goods inventory which we denote by $\tilde{I}_{2}(t)$ for $i=V^{c}+1 \ldots \ldots$. the product that is currently set up (or being set up). and the residual service and setup times (if they are currently in progress).

The machine follows a dynamic cyclic policy: All products are serviced in a fixed cycle. At any point in time the scheduler can deploy the machine in one of three ways: Produce the product currently set up for (this might not be possible if set up for a customized product and there are no orders present). set up for the next product in the cycle. or idle. The policy is dynamic in that the lot sizes and the busy/idle policy can be molded to address the changing needs of the stistem.

A penalty is incurred every time the machine switches production to the next product in the crole. This penalty can be a cost. a period of dorntime or both. The hearr traffic

performance of the system depends on these penalties only through the average setup cost per cycle. $\tilde{H}$. and the average total switchover time per cycle.s. If only one form of setup penalty is present and setups vary by product. then the best cycle order can be found by solving a traveling salesman problem. where the distance bet ween two cities corresponds 10 the setup penally between two products. If both forms of penalties are present then the situation is more complex. We also assume that the policy is preemptive-resume, but the approximation scheme used here is too coarse to differentiate between a system with a preemptive-resume policy versus one without preemption.

We wish to minimize the long run expected average cost of the system. and additional notation is required to describe our objective function. Let $T_{n}$, be the time that the $n^{\text {th }}$ unit of product $i$ is assigned to an order. When a completed unit is assigned to an order. we assume that it is assigned to the order with the earliest due-date within its product. as this will minimize cost (see Pandelis and Teneketzis 1995 and Righter 1996). For $t \geq 0$. define the minimum slack $\dot{L}_{1}(t)$ to be the smallest slack among all orders in product is queue at time $t$. Finally: let $\vec{J}(t)$ be the cumulative number of cycle completions by time $t$. The long run arerage cost is

$$
\begin{array}{r}
\limsup _{T \rightarrow \infty} \frac{1}{T}\left(\sum_{i=1}^{N^{c}} \sum_{\left\{n \mid T_{n i}<T\right\}}\left[\hat{h}_{i} \dot{L}_{i}^{+}\left(T_{n i}\right)+\hat{b}_{i} \tilde{L}_{i}^{-}\left(T_{n 2}\right)\right]\right.  \tag{1}\\
\left.+\sum_{i=N^{-}+1}^{\times}\left[\int_{0}^{T} \hat{h}_{1} \bar{I}_{i}(t) d t+\sum_{\left\{n \mid T_{n i}<T\right\}} \hat{b}_{i} \dot{L}_{\imath}^{-}\left(T_{n i}\right)\right]+K^{\prime} \bar{J}(T)\right) .
\end{array}
$$

where $x^{+}(t)=\max \{x(t) .0\}$ and $x^{-}(t)=\max \{-x(t) .0\}$. Notice that the multiplicative product of cost and queue length is integrated over time for the items in finished goods inventory. Whereas we have chosen to sum the product of cost and time (e.g. $\hat{h}_{i} \tilde{L}_{2}^{+}\left(T_{n, 2}\right)$ ) over orders. This "reversal of the order of integration" is a necessary step in analyzing the effects of due-dates.

## 2. HEAVY TRAFFIC PRELIMIINARIES

This section provides an overview of the heary traffic analysis of the problem described in §1. The approach outlined here relies hearily upon results in Coffman. Puhal-

skii and Reiman and MIRIW. and we refer readers to these papers for more details.
Workload Processes. We begin by defining the key stochastic processes for our heary traffic analysis. Recall that the system has queues of orders for all products and a finished goods inventory of items for all standardized products. For customized products $i=1 \ldots \ldots N^{c}$. let $\tilde{H}_{i}(t)$ be the total amount of time required for the machine to process all of the orders that are in product is queue at time $t$. For standardized products $i=N^{c}+1 \ldots \ldots V^{\prime}$. let $\tilde{I}_{i}(t)$ be the total amount of time needed to process all standardized orders of product $i$ minus the total machine time already invested in the units in product is finished goods inventory at time $t$. We refer to $\tilde{I}_{i}=\left\{\tilde{I}_{i}^{\prime}(t), t \geq 0\right\}$ as the workload process for product $i=1 \ldots \ldots . \operatorname{l}$. and let $\tilde{I}^{-}=\sum_{i=1}^{v} \tilde{H}_{i}$ be the total workload process. The total workload at time $t$ represents the total amount of work currently being requested (in the form of orders) minus the total work stored in inventory (this work will eventually be assigned to orders). This one-dimensional process is the natural definition of workload for systems with customized and standardized products: readers should note that. in contrast to MRUT. the total workload is defined from the "make-to-order" point of view. in that work in orders is positive and work in finished goods inventory is negative.

Heavy Traffic Averaging Principle. Coffman. Puhalskii and Reiman's heary traffic averaging principle (abbreviated by HTAP) has augmented the understanding of heavily loaded multiclass queueing systems that incur setup costs or setup times. Although rigorously proved for a two-class queue (in the absence and presence of setup times in 1995a and 1995b. respectively) that employs an exhaustive service discipline. numerical results in Reiman and Wein (1994. 1996). MRIV and Reiman. Rubio and Wein support the conjecture that the HTAP holds for a much wider class of systems. As in these applications. we conjecture that the HTAP holds without providing a rigorous proof of convergence.

The HTAP is based on two sets of limits. taken as the total utilization goes to one and synchronized by a scaling parameter $n$. The first limit of the IITAP states that as $\sqrt{n}(1-$ $\rho)$ approaches a constant $c$. the normalized total workload process $\tilde{I I}^{\prime}(n t) / \sqrt{n}$ weakly converges to a diffusion process. $W^{\prime}(t)$. with parameters defined by the system data and

policy. It is called the diffusion limit and is the result of a functional central limit theorem. The second limit, called the fluid limit, states that for the same scaling parameter $n$ and for a given total workload. the individual workloads in $;(\sqrt{n} t) / \sqrt{n}$ converge almost smedy to $\mathbb{H}_{i}(t)$, a fluid process; this result is related to the functional strong law of large numbers.

The time scale decomposition inherent in these two limits is intuitive: As utilization approaches one, the amount of work in the system is large and the total workload cannot change quickly; yet, as the machine switches between products, work can shift rapidly among the individual queues and inventories. The shifting of individual workloads orcurs an order of magnitude. $O(\sqrt{n})$. more quickly than the total workload, and so the fluid limit evolves for a period while the total workload remains relatively constant. For example. the total workluad might change on the oreter of weeks, while individual workloads change daily:

Dynamic Cyclic Policies and the Fluid Limit. Under a dynamic cyelic policy: a service cycle corresponds to the setting up and processing of each of the $I$ products. If the machine is following a dymamic cyclic policy. then the HTAP implies that many cycles will be compteted before there is a significant change in total workload If (t). Because there are many cyeles for a given total workload. a dynamic cyclic policy can be expressed as a function of only the total workload level. not the individual workloads: i.e. the lot sizes for each product and the busy/idle policy depend only on the total workload level. MRW show that dymanie cyclic policies in heary traffic can be completely characterized by an idling threshold $w_{0}$ and two workload-dependent functions, the $N$-dimensional cycle center $x^{c}(w)$ and the cycle length $\tau(w)$ (throughont. we denote the total workload process by $I I$ and an arbitrary feasible total workload by w . The fluid process is unaffected by the idling threshold. and is dictated by the latter two functions. The $i^{\text {th }}$ element $x_{2}^{c}\left(w^{\prime}\right)$ of the cycle center is the average amount of work in product $i$ over the course of a cycle in the fluid limit. The cycle lengtly $\tau(w)$ is the amount of time required to complete a cyele in the fluid limit. For the inventories and quenes to remain balanced. the machine must allocate $p_{2} \tau\left(u^{\prime}\right)$ units of time per cycle producing product $i$. White prodnct $i$ is in service the process 11 i decreases at rate $\left(1-\rho_{2}\right)$, while the machine is set

up for other products. Wi increases at rate $\rho_{2}$ (perhaps by depleting the fimished goods inventory for $i=V^{c}+1 \ldots, N$ ). Setup times are unsealed (i.e., remain $O(1)$ ) and wanish in the fluid limit: The large amonnt of work in the system causes setups to be performed relatively infrequently. Thus. product i's workload level fluctuates by $p_{2}\left(1-p_{2}\right) \tau\left(w^{\prime}\right)$ over the course of a cycle, and ranges from a minimum of $x_{2}^{c}(w)-p_{2}\left(1-p_{2}\right) \tau(w) / 2$ to a maximum of $x_{i}^{c}\left(w^{\prime}\right)+\rho_{i}\left(1-\rho_{i}\right) \tau\left(w^{\prime}\right) / 2$. The cycle center and cycle length are parameters that can be set by the scheduler, subject to some restrictions: The sum of the cycle centers must equal the total workload. $\sum_{i=1}^{V} x_{i}^{c}(w)=w$; the minimmum amount of work over the cycle must be nomegative for a customized product, $x_{2}^{c}(w)-\rho_{2}\left(1-\rho_{2}\right) \tau(w) / 2 \geq 0$; and if there are setup penalies then the cycle length $T(w)$ must be greater than zero.

Cost per Cycle. Given the dymamics described above, we can express the cost of a fluid cycle, $c(u)$, in terms of the parameters $x^{c}\left(u^{\prime}\right)$ and $\tau\left(u^{\prime}\right)$. The cost per cycle is composed of indisidual prorluct (earliness. tardiness and holding) costs and setup costs. and is given les

$$
\begin{equation*}
r\left(u^{\prime}\right)=\sum_{i=1}^{N} c_{i}\left(\cdot x^{c} \cdot \tau \cdot u^{c}\right)+\sum_{i=N^{c}+1}^{N} c_{i}\left(x^{c} \cdot \tau, u^{v}\right)+\frac{K}{T\left(u^{c}\right)} . \tag{2}
\end{equation*}
$$

where $c_{2}\left(x^{*}, \tau, u^{\circ}\right)$ is product $i$ s average cost rate for a cycle given a policy $x^{c}$ and $\tau$ and total workload $u$, and $k=\dot{K} / n$ is the normalized setup cost per cycle (see Reiman and Wein 1994 for a justification of this scaling). In MRW, we calculated $c_{2}\left(x^{c}, \tau_{,}, w^{\prime}\right)$ by integrating the cost over one production cycle and then dividing by the cycle length. In the next section, we perform the same type of calculation for our due-date problem but "interchange the order of integration" as discussed before. That is, instead of integrating over time in the cycle. we integrate over the orders filled during the cycle.

Dynamic Cyclic Policies and the Diffusion Limit. Coffman. Puhalskii and Reiman show that the drift of the diffusion process for total workload level $\omega^{*}$ is $s / \tau(w)-c$. When there are no setup times. the diffusion limit is a reflected Brownian motion (RBAI). regardless of the policy in use: this result coinciles with classic results (Iglehart and Whitt 1970). Since the cycle length $\tau\left(u^{\circ}\right)$ is dictated be the dyamic erclic policy: the drift of the diffusion process depends on both the policy and setup times when setup times are
$-\infty-4 \quad$,
$+2-\cdots+4$

-1 -1,

present. The variance of the diffusion process is $\sigma^{2}=\sum_{i=1}^{X} \frac{1}{\mu_{1}^{2}}\left(f_{12}^{2}+c_{s 2}^{2}\right)$, and thus is onty dependent on system parameters.

Alhough the idling threshoki wo does not affect the fluid process. this control parameter does impact the one-dimensional diffusion process If by acting as its reflecting barrier. There are restrictions on $w_{0}$ only if there are no standardized goods in the system. In this case, woust be nonnegative.

The Optimization Problem. Suppressing the notation illustrating the dependence of the cost on our policy, we can express the objective function in equation (1) as

$$
\begin{equation*}
\limsup _{T \rightarrow \infty} \frac{1}{T} \int_{0}^{T} c\left(H^{\prime}(t)\right) d t \tag{3}
\end{equation*}
$$

Where $c(u)$ is given in (2). Our controls are the idting threshold wo and the $N$-dimensional functions $x^{c}\left(w^{\prime}\right)$ and $\tau\left(w^{\prime}\right)$. As in NHKIV, the uptimization is carried ont as lohtows. We minimize ( 2 ) with respect to $x^{c}$ to find the cycle center in terms of $\tau\left(w^{\prime}\right)$ and $u_{0}$. Fhis is a constrained nonlinear optimization problen. Then (3) becomes a diffusion control problem with a drift control (wia the cycle length $T\left(w^{\prime}\right)$ ) and a singular control (wia the idlling threshold $\left.u_{0}\right)$.

## 3. OPTIMAL DYNAMIC CYCLIC POLICIES

The gual of this section is to optimize the cost in (3). This optimization is performed in several steps: $\ln \{3.1$ and $\} 32$. we calculate the cost function $c_{1}\left(x^{c}, T, w^{\prime}\right)$ in (2) for customized and standardized products. respectively. To ease readability in these two subsections. we suppress the notation depicting the dependence of the fluid processes and policies on a fixed total workload $w$. Then we perform the cost minimization in $\oint 3.3$ and translate the solution into a dynamic eyclic policy for the uriginal queueing control problem in $\S 3.1$.
3.1. Customized Products. The primary challenge in catculating $c_{2}(x$. T. W) is to determine how due-dates affect this cost function in the fluid limit. We begin be nomatizing the due-date lead times. Becanse queue lengths and waiting times are typically $O(\sqrt{n})$ in heavy traffic models. it is appropriate for due-date lead times to also

be $O(\sqrt{n})$. Therefore, we assume that the due-date lead time density $f_{2}(\sqrt{n} s)$ converges to the nontrivial density $f_{2}(s)$, with cmmalative elistribution function $F_{2}(s)=\dot{F}_{2}(\sqrt{n} s)$ and mean $\bar{l}_{1}=\bar{l}_{2} / \sqrt{n}$. In cont.ast. under a diffusion time scaling the density $\tilde{f}_{2}(n, s)$ comerges to a point mass at $s=0$ and is zero elsewhere. Hence. due-dates do not appear in the diffusion process and are isolated in the fluid limit. This state of affairs is consistent with the heary traffic snapshot principle (see Reiman), which states that a customer's sojourn in the systen is instantaneous under the diffusion scaling.

Let $L_{2}(t)=\dot{L}_{2}(\sqrt{n} t) / \sqrt{n}$ denote the minimum stack process in the fluid system, and define the process $D_{2}(s, t)$ to be the amount of product $i$ work present in the system at time $t$ that is due at time $s+t$; in other words. $\tilde{D}_{2}(s, t)$ is the work present at time $t$ that has stach s. Let $D_{2}(n, t)=D_{2}(\sqrt{n} s . \sqrt{n} t) / \sqrt{n}$ lenote its fluid limit. Notice that $D_{2}(s, t)$ provites a more detailed description of the orders than if: $(t)$.

Equation (1) shows that the key to calcutating the cost function is to determine the behavier of the minmum slack $L_{n}(t)$ thronghont the course of the cycle. The cost function $c_{1}\left(r^{c}, \tau, u^{4}\right)$ is derived in three steps (in Proposition 2. Proposition 3 and equation (11), respectively): We calculate the process $\bar{D}_{2}(s, l)$ in terms of the original problem parameters and the mimimum slack at the start of the cycle. derive $\bar{L}_{2}(t)$ in terms of the process $\bar{D}_{2}(s, t)$ (in these first two steps. we replace $D_{2}(s, t)$ by a process closely retated to it. as explained after Propusition 1). and express the cost function $c_{2}\left(r^{c} \cdot T . w^{\prime}\right)$ in terms of $L_{\ell}(t)$.

Withont loss of generality. we assume that a cycle for product i starts at time zero ant service is received from time $\left(t-\rho_{2}\right) \tau$ to $T$. Hence, the amount of product $i$ work in the system at the start of a cycle. Which we denote by $x_{2}^{s}$, is equal to $x_{2}^{c}-\tau p_{2}\left(1-p_{2}\right) / \ddot{0}$. The initial work $x_{i}^{s}$ must be stored in the system as orders with the-date lead times greater than or equal to $L_{2}(0)$. by definition the smallest slack among product $i$ orders in the system at time zero. The relation between $D_{2}(s, t)$ and the workload $W_{i}(t)$ at time zere, is given by the following proposition, where $F_{2}(n)$ is defined as $t-F_{2}(6)$.

Proposition 1 . It timt $t=0$.

$$
D_{\imath}(s, 0)= \begin{cases}\rho_{2} F_{2}^{c}(s) & \text { if } s \geq L_{2}(0) \\ 0 & \text { if } s<L_{\imath}(0)\end{cases}
$$

and

$$
\begin{equation*}
x_{i}^{s}=\int_{\tilde{L}_{s}(0)}^{\infty} \rho_{2} F_{i}^{c}(s) d s \tag{5}
\end{equation*}
$$

Proof: Because the product $i$ workload arrival process is deterministic and flows in at rate $\rho_{i}$ under the fluid scaling, at any $d t$ instant of time $\bar{f}_{i}(s) \rho_{2} d t$ units of work due in $s$ units of time arrive in the thuid limit. The work in the system at time $t$ with slack $s$ is bounded by he maximum amount of work that could have arrived with a due-date of $t+s$. At time zero, the maximm amount of work present with slacks is the recently arrived work plus work that arrived $r$ units in the past with a due-date of $s+r$. Notationally this is $\int_{0}^{\infty} \rho_{2} \bar{f}_{2}(n+r) d r$. which is equal to $p_{2} \bar{F}_{2}^{c}(s)$. Thus, $\bar{D}_{2}(s, 0) \leq \rho_{2} \bar{F}_{2}^{c}(s)$. This inequality is strict if orders due after time $L_{2}(0)$ were worked on. Since an earliest due-date policy is being used and the machine processes work at rate une, which is strictly greater than $\rho_{2} F_{i}^{c}(s)$, it follows that $D_{2}(s, t)$ at the next instant either wanshes or is untonched bs service and only affected by arrivals. At time zero, the machine has just switched out of producing product $i$, implying that the work due after time $L_{2}(0)$ has not been touched and that there has been no opportunity for orders to arrive with due-date lead times below $L_{2}\left(0^{-}\right)$, the smallest slack the instant before the switchover. Thus, equation (4) holds. By construction, we lave $x_{2}^{s}=\int_{L_{,}(0)}^{\infty} \bar{D}_{2}(s, 0) d s$. Combining this with equation (4) yields equation (5).

Because the interaction of $D_{1}(s, t)$ and $L_{2}(t)$ is complex. we streamline our calculations by creating a simplified variant of $\bar{D}_{2}(s, t)$ that evolves through the course of one cycle. Let $\bar{D}_{i}^{N}(s . t)$ be the amount of work at time $t$ with slacks if the machine performs no work for product $i$ from $t=0$ until $\tau ; D_{i}^{*}(s, t)$ is only defined for $t \in[0 . \tau)$. Thus. $D_{2}^{N}(s, t)=D_{2}(s, t)$ for $s \geq L_{2}(t)$ but is not necessarily 0 for $s<L_{2}(t)$. The process $D_{i}^{V}(s, t)$ is useful for two reasons: Its behavior is casy to describe. and $I_{2}(t)$ can be derived directly from it. The evolution of $\bar{D}_{2}^{V}(\ldots t)$ is described by the fullowing proposition.

Proposition 2 For $t \in[0, \tau)$.

$$
D_{i}^{V}(s, t)=\left\{\begin{array}{ll}
\rho_{i} F_{i}^{c}(s) & \text { if } s \geq L_{i}(0)-t  \tag{6}\\
\rho_{i}\left(\dot{F}_{i}^{c}(s)-\bar{F}_{i}^{c}(s+t)\right) & \text { if } s<\bar{L}_{i}(0)-t
\end{array} .\right.
$$

Proof: By construction. $D_{i}^{N}(s, t)$ evolves according to the differential equation

$$
\begin{equation*}
\bar{D}_{2}^{\nu}(s . t+d t)=\bar{D}_{2}^{v}(s+d t . t)+\rho_{2} \bar{f}_{2}(s) \tag{7}
\end{equation*}
$$

That is, the amonnt of product $i$ work in the system at time $t+d t$ that is due at time $t+s+d t$ is equal to the amount of work that was previously in the system at time $t$ with slack $s+$ dt plus the amount of work with a due-date lead time of $s$ that has just arrived. Using the fact that $D_{i}^{\prime}(s . t)$ equals $D_{\imath}(s, t)$ at $t=0$. rearders can verify that

$$
D_{2}^{\prime}(s . t)=\rho_{2}\left(F_{2}^{c}(s)-\bar{F}_{2}^{c}(s+t)\right)+\bar{D}_{2}(s+1.0)
$$

is the solution to equation (7). The proposition follows by using equation (1) to substitute in for $D_{2}(s+t, 0)$ in ( $S$ ).

In an attempt to enlance the reader"s intuition, we point out some noteworthy features regarding the evolution of $D_{i}^{\prime}(s, 1)$ in Figure 2. For the sake of concreteness. Figure ᄅa contains a uniform due-date lead time distribution, with fluid minimum and maximum of $\bar{a}_{2}=a_{2} / \sqrt{n}$ and $b_{2}=b_{2} / \sqrt{n}$. Figures $2 b-2 d$ display: for a fixed value of $t$. $D_{i}^{\gamma}(s, t)$ as a function of $s$ under three cases depending on the relative value of $L_{2}(0)$. $\bar{a}_{2}$ and $\bar{a}_{2}+t$. Athough this figure represents smapshots of $D_{2}^{V}(s, t)$ at a fixed time $t$, it is perhaps more instructive to describe the dynamics of $D_{i}^{V}(s, t)$ as $t$ increases. As time $t$ progresses through the cycle, the existing orders age and new orders arrive. A useful metaphor is to imagine the area under the curves in Figures $2 b-2 d$ as water. the curves as waves, and new orders as raintrops accumulating on the waves. Then the waves of work travel to the left (i.e.. slack is decreasing) in Figures 2 b- $2 d$ as time progresses. and grow in height as new orders are added to them. Notice that work with slack $L_{2}(0)$ at time zero has slack $L_{2}(0)-1$ at time $t$ if no work is performed during the cycle By

equation (6). for slacks s exceeding this critical value, the work at time t that has slack o is $\bar{D}_{i}^{V}(s, t)=p_{i} F_{i}^{\prime}(s)$. For these slack values, which correspond to the regions in Figures $21-2$ to the right of $L_{2}(0)-t$, the quantity $D_{i}^{V}(s, t)$ is in equilibrimm: The amount of work that is aging equals the amount of work that is amiving for all values of $\mathrm{s} \geq \bar{L}_{i}(0)-\ell$. and so the shape of the waves in Figures $2 \mathrm{~b}-2 \mathrm{~d}$ to the right of the barrier $L_{2}(0)-t$ are invariant over time $t$. For a fixed time $t$ in these equilibrium regions, $D_{2}^{2}(s, t)$ is proportional to the complementary cumulative distribution function of the due-date lead time. and so $\bar{D}_{i}^{V}(s, t)$ drops to zero at the point $s=\bar{b}_{2}$. Also, for $s \in\left[\bar{L}_{i}(0)-t, a\right], \bar{D}_{i}^{N}(s, t)$ is constant and takes on its maximum value of $\rho_{2}$ (see Figures 2 b and ${ }^{2} \mathrm{c}$ ) ; here, all of the work that could be due at time $s+t$ has arrived.

By Propusition 1. at time $t=0, D_{i}^{N}(n, 0)$ has the equilibrium value $p_{2} F_{i}^{c}(s)$ for $s \geq L_{2}(0)$ and 0 otherwise. Huwerer, the evolution over the cycte of $\bar{D}_{i}^{V}(s, t)$ has two different qualitative structures depending on if the earliest possible arriving due-date lead time $a_{2}$ is greater than the initial minimum slack $\bar{L}_{1}(0)$. or less than it. If $\bar{L}_{2}(0)<$ $\bar{a}_{2}$ then no new orders will have a slack less than those that had a slack of $\dot{L}_{2}(0)$ at time zero. Therefore, orders arrive with just the correct due-date lead time distribution to maintain the equilibrium behavior of $D_{i}^{v}(s, 0)$, as elisplayed throughout Figure $2 b$. However. if $L_{2}(0)>a_{2}$ then new orlers can arrive with a due-date leard time smaller than the minimum slack of the orders present at time zero. In this case, as time $t$ progresses. a small amount of orders with slacks less than $L_{\imath}(0)-t$ accumulates but never exceeds $\rho_{2} F_{1}^{c}\left(L_{t}(0)-t\right)$. Which is the quantity of work in the systen at time $t$ with due-date leattime $L_{\imath}(0)-t$ (see Figure $2 d$ ). Thus, the critical slack value of $\bar{L}_{2}(0)-t$ marks the barrier between the equilitrium work level $\rho_{t} \bar{F}_{2}^{c}(s)$ (to the right of the barrier) and the accumulation of new orders with small due-date learl times (to the left of the barrier). Finally, referring to the portion of the curve to the left of the barrier in Figures $2 b-2 d$. in the region $s<L_{2}(0)-t$. all of the work in $L_{2}(0)$ is due after time $s+t$. and hence $D_{i}^{V}(s, t)$ must equal zero for $s<t_{t}-t$ : this ratical value of $s$ corresponds to an order arriving at time zero with the minimum due-tate lead time of $a_{2}$.

Akdous. Kelly and Lehoczk! (1995) use heave traflic theory to analyze the performance of a single-class Cil/(i/l queue with random due-date lead times that operates

$$
\begin{align*}
& \text { Due-date Lead Time Density } \\
& \overline{f_{1}} \\
& \bar{L}_{i}(0)<\bar{a}_{i} \\
& \rho_{2}{ }^{-1} \\
& \bar{D}_{i}^{\prime} \text { (s.t.) }  \tag{b}\\
& \bar{a}_{2}-t \quad L_{i}(0) \sim t \quad \bar{a}_{2} \\
& \bar{a}_{2}+t<\bar{L}_{i}(0) \\
& \bar{D}_{i}^{〉}(s, t)  \tag{d}\\
& \bar{a}_{2}-1 \quad \bar{a}_{2} \quad I_{2}(0)-t \\
& \text { (id) } \\
& \text { S } \\
& \checkmark \\
& b_{1} \\
& \bar{a}_{i}<\bar{L}_{i}(0)<\bar{a}_{i}+t \\
& p_{2}- \\
& \bar{D}_{i}^{V}(s, t)  \tag{c}\\
& b_{i}
\end{align*}
$$

Figure 2: The function $D_{1}^{\prime \prime}(\cdots, t)$ as a function of $s$.
under the first-come first-served discipline. They derive a figme that is essentially identical to Figure 2b). Because there are no setups and only one product, the non-equilibrium region to the left of the due-date lead time barrier $L_{2}(0)-t$ does not appear in their problem.

Onr next step is to calculate the minimmon slack process $L_{2}(t)$ in terms of $\bar{D}_{2}^{\mathrm{V}}(\mathrm{s} . t)$. When the machine is servicing other products, the order with the earliest due-date corresponds either to the earliest due-date request just as the server switched out of product $i$ (i.e. $\left.\bar{L}_{2}(0) \leq \bar{a}_{2}\right)$ or the request with the due-date lead time of $\bar{u}_{i}$ that just arrived after the machine switched out (i.e., $L_{i}(0)>a_{2}$ ). Thus, we have

$$
\begin{equation*}
L_{2}(t)=\min \left[a_{2}-t, L_{2}(0)-t\right] \text { for } t \in\left[0 . T\left(1-\rho_{2}\right)\right) . \tag{9}
\end{equation*}
$$

Recall that $D_{i}^{2}(n, t)$ was constructed under the assumption that the machine does not work on prorluct, throughout the eycle. When product $i$ is being served, the machine consumes the left must part of the curves in Figures $2 b-2 d$ (in the context of our metaphor, the machine swallows the water at a constant rate). For $t \in\left(\tau\left(1-p_{t}\right), \tau\right)$. the server would have completed $t-T\left(1-p_{2}\right)$ units of work. Since the machine works according to the earliest due-tate rule whitheach product. Work corresponding to $D_{i}^{N}(s, t)$ for s below $L_{2}(t)$ has heen completed. Thus we have the following proposition.

Proposition $3 L_{2}(t)$ is the smallest quantity that satisfies

$$
\begin{equation*}
t-\tau\left(1-\rho_{2}\right)=\int_{-\infty}^{L_{t}(t)} D_{i}^{v}(s, t) d s \quad \text { for } \quad t \in\left(\tau\left(1-p_{2}\right) . \tau\right) \tag{10}
\end{equation*}
$$

Equations (5), (9) and (10) aniquely determine $\bar{L}_{2}(t)$ orer the courst of ont cepete.
Equations (5). (9) and (10) can be used to express the minimum slack process $L_{2}(t)$ over the course of one cycle solely in terms of the initial minimum slack and the primitive probabilistic processes of the problem (although we do mot write ont this expression here). In addition. We can summarize the qualitative hehavior of the minimum slack process. From time zero matil time $\tau\left(1-\rho_{2}\right)$ ne services occur and only orders arrive to the quene. Since orders age and get closer to their due-date. the minimmon stack in protuct i. $l$. (t).

is monotonically decreasing at unit rate for $t \in\left(0, \tau\left(1-p_{2}\right)\right)$, as seen in (9). From time $\tau\left(1-\rho_{2}\right)$ until $\tau . L_{2}(t)$ is monotonically increasing beeause the service rate is always greater than $D_{2}(s, t)$ (i.e., orders are being filled faster than they can age), although its behavior is more complex. If $L_{i}(0)<\bar{a}_{i}$ then, when the machine begins working on product $i, L_{i}(t)$ increases linearly until the end of the cycle; referring to Figure 2b, the machime is consuming the flat part of the curve and $\bar{L}_{2}(t)$ does not reach $a_{2}$ before the end of the cycle. If $L_{i}(0)>\bar{a}_{i}$ then the rate of increase is volatile, moving quickly through the region to the left of the barrier $L_{2}(0)-t$ in Figures 2e and 2d. dramatically slowing when the barrier is passed and then speeding up again as the right tail (represented by $\rho_{l} F_{i}^{c}(s)$ in Figures 2c and 2d) is reached.

Our firal step is to determine product i's average inventory cost per cycle in terms of $L_{\imath}(t)$ for a given cycle center $x_{\imath}^{c}$ and cycle length $\tau$. It. is equal to the average of the earliness or tardiness costs associated with orders as they are filled. Since the machine follows an earliest dut-date policy, the earlimess or tardiness of an order filled at time $t$ is either $L_{A_{2}}(f)$ or the due-date lead time associated with a current arrival if that arrival has a due-date lead time less than $\bar{L}_{2}(t)$. If there are arrivals with due-date lead times s less than $\bar{L}_{2}(t)$, then the machine spends $p_{2} f_{2}(. s)$ fraction of effort on them and $1-\rho_{2} \bar{F}_{2}\left(\bar{L}_{2}(t)\right)$ fraction of effort on orders with slack $L_{2}(t)$. Thus the average cost for a product $i$ order is

$$
\begin{equation*}
c_{2}\left(v_{2}^{c}, \tau, w^{\prime}\right)=\frac{1}{\tau} \int_{\tau\left(1-\rho_{1}\right)}^{T}\left(b_{2} L_{2}^{-}(t)+h_{2}\left[\left(1-\rho_{2} \bar{F}_{2}\left(L_{2}(t)\right)\right) L_{2}^{+}(t)+\int_{0}^{L_{1}(t)} p_{2} \bar{f}_{2}(s) \cdot \cdot d s\right]\right) d t \tag{11}
\end{equation*}
$$

Although this cost function is complex, the average cost per cycle is computable. The HTAP has dramatically simplified the problem. As noted in $\xi 1$, the state of the system in a Markov decision process framework is unwieldy because the evolution of orders with due-dates needs to be tracked over time. The fluid limit has transformed order progression through this complex state space into $\bar{D}_{2}(s, t)$. From a functional analysis point of view, the ideas are similar because $D_{2}(\cdot, t)$ is a bounded function on a compatt domain and so is a point in the infinite-dimensional space of square integrable functions $L^{2}$. The fluid limit thens approximates the evulution of orders in the system as a path
in $L^{2}$. parameterized by the index $t$ in $D_{2}(\cdot, t)$. Athongh this relationship is abstrast. the path in $L^{2}$ is made computationally tractable by Propositions 1-3. Noreover, by "reversing the order of integration," we are able to take adrantage of this tractability and translate $D_{2}(s, t)$ into an average cost per cycte.
3.2. Standardized Goods. The cost calculations for standardized products are more complex than in the customized case because the queue of orders and the inventory of completed items are embedded in the products' workluad. Let II $_{t}^{\prime!}(t)$ represent the amount of product $i$ work in finished goods inventory at time $t$ (i.e.. the amonnt of machine time embedded in $\left.\dot{I}_{2}(t)\right)$, and let $\Pi_{i}^{\prime}(t)=\prod_{i}^{I}(\sqrt{n t}) / \sqrt{n}$ be its flnid counterpart. An important aspect of ${W_{2}^{-I}(t) \text { is that it must be nonnegative as it represents actual goods }}_{\text {a }}$ in inventury: backorders are in the form of unfilled orders in $D_{i}(s, t)$. We assume. as in the customized case, that at time zeru the server has just switched out of product $i$. Because $D_{i}^{N}(\cdots, t)=D_{2}(\cdots, t)$ for $n \geq L_{2}(t)$. the workload process $H_{i}(t)$ can be expressed as

$$
\begin{equation*}
\tilde{H}_{i}(t)=\int_{\tilde{L}_{2}(t)}^{a} D_{2}^{V}(s, t) d s-\tilde{H}_{2}^{l}(t) \text { for } t \in[0, T) . \tag{2}
\end{equation*}
$$

Recall that we do not assign completed units to standardized orders before their due-date. This leads to 1 he important observation that $L_{2}(t) \leq 0$ for all $t$. The rational for this is simple: If for some unexplamable reason $L_{2}(t)>0$ (for instance when a rare event suddenly shifts the total workhad level $\left.H_{i}(t)\right)$ then we assign no completed units to orders ant instead place them in finisherl goods inventory: The minimum slack $L_{2}(t)$ then decreases to zero and never again goes higher. This is a transitory elfect that will be washed away after the repetition of several cycles and so can he ignored. Hence. by equation (6) we can conelude that

$$
\begin{equation*}
D_{i}^{V}(s, l)=r_{i} F_{i}^{c}(s) \text { for } s \geq 0 \text { and } \quad t \in[0 . T) \tag{1:3}
\end{equation*}
$$

Because unts from inventory are aflocated to prevent backorders, it follows that $L_{2}(t)<0$ only when $H_{i}^{\prime \prime}(t)=0$ : i.e.

$$
\begin{equation*}
H_{1}^{-I}(t) L_{2}(t)=0 \text { for all } t \tag{11}
\end{equation*}
$$

So if $L_{t}(t)<0$ then the next unit of product i completed by the machine is assigned to the product i order with the earliest due-date, and a tardiness cost is incurred. Completed units that are not assigned to ortors are placed in the finished goods invent ory represented by $\bar{H}_{2}^{I}(t)$ and accumulate a bolding cost. Therefore, the cost per cyele for a standardized product is

$$
\begin{equation*}
c_{2}\left(x_{i}^{c}, \tau, w^{c}\right)=\frac{1}{\tau}\left[\int_{\tau\left(1-\rho_{t}\right)}^{\tau} b_{i} L_{2}^{-}(t) d t+\int_{0}^{\tau} h_{2} H_{i}^{-I}(t) d t\right] . \tag{15}
\end{equation*}
$$

Equations ( 120 -(14) lead to the useful relation that $\tilde{F}_{2}^{-I}(t)$ is positive only if $\mathbb{F}_{2}(t)<$ $\int_{0}^{\infty} \rho_{2} F_{i}^{c}(s) d s$, and so $H_{i}^{I}(t)=\left(H_{2}^{\prime}(t)-\rho_{2} \tilde{l}_{i}\right)^{-}$. It is important to note that we alrearly know the behavior of $\bar{W}_{2}(t)$ for standardized protucts from MRW: Thus, the holding cost portion of the cost per cycle in (15) is just a translation in terms of workload (or equivalently, cycle center $x_{2}^{c}$ ) by $p_{2} l_{2}$ of the stochastic economic lot scheduling problem (SELSP) hokling cost.

Now we turn to the tardinest costs in (15). Because $L_{2}(t)<0$ when tardiness costs are incurred. it follows by $(12)$-(14) that

$$
\begin{equation*}
W_{i}(t)=\int_{L_{t}(t)}^{0} D_{i}^{x}(s, t) d s+\int_{0}^{\infty} \rho_{2} F_{i}^{c}(s) d s \tag{16}
\end{equation*}
$$

during these times. To detemine $D_{i}^{V}(s, t)$ in the first integral, we observe that $L_{0}(t) \geq$ $L_{2}(0)-t$ by $(9)$ and the fact that $L_{2}(t)$ is nondecreasing for $t \in\left(\tau\left(1-\rho_{t}\right) \cdot \tau\right)$. Hence. $\therefore \geq L_{2}(0)-t$ in the first integral. and so $\bar{D}_{2}^{V}(s, t)=\rho_{2} F_{i}^{c}(s)$ by Proposition 2. Because $s \leq 0$ in this integral, equation (16) becomes $\|_{2}(t)=\int_{L_{1}(t)}^{0} \mu_{2} d s+\rho_{2} l_{2}$. We conclude that in the backorder regions

$$
\begin{equation*}
\rho_{i} L_{i}^{-}(t)=\left(\bar{H}_{2}^{+}(t)-\rho_{2} l_{2}\right)^{+} . \tag{17}
\end{equation*}
$$

By equations (15) and (17), the time average tardiness cost for a given tot workload is

$$
\begin{equation*}
\frac{b_{2}}{p_{2} T}\left[\int_{\tau\left(1-p_{t}\right)}^{T}\left(\| I_{i}(t)-p_{2} l_{2}\right)^{+} d t\right] . \tag{1N}
\end{equation*}
$$

Again. this is a translation of the SELSP rost per cercle.
Therefore the cost per crole for stambardized gourls with due-dates is exartly the same as the SEISP cost with a cycle conter shift by pro. which is just pronluct is

utilization times its mean due-date leat time. For a system with only standardized products, it follows that the optimal switching curves are shifted by pil from the SELSP case, and the cost is independent of the due-date lead times: this important observation is discussed further in §4.5. §5.6 and §5.8. Thus. as in MRW, $c_{2}\left(x^{c} . \tau, w^{\prime}\right)$ is broken down into three regions based on if there is only holding, only backortering or mixed costs over the cycle. The cost per cycle can be expressed as
3.3 Optimization. With an expression for average cust for each level of workload in hand, we can optimize over the dymamic cyclic policy as determined by $x^{6}$. $\tau$ and $w_{0}$. The gemerality of the due-date lead time distribution prevents an exact solution. A numerical procedure however, is possible. Policy optimization must be performed on both the fluid and the diffusion levels.

Tuder the fluid scalings, the cyele center $x^{c}$ can be optimized with respect to a given cycle length $\tau$ and total workload level $u$. This nonlinear program can be stated as follows:

$$
\begin{align*}
& \min _{x_{r^{c} \in R^{v}}} \sum_{i=1}^{Y} c_{i}\left(x^{*} \cdot \tau, w^{n}\right)  \tag{20}\\
& \text { such that: } \quad \sum_{i=1}^{l} x_{2}^{c}=w  \tag{21}\\
& \left.r_{i}^{c} \geq \frac{\tau_{1}\left(1-\rho_{i}\right)}{2} \text { for } 1=1 \ldots \ldots\right)^{\prime} \text {. }
\end{align*}
$$

The highty nonlinear aspects of $L_{2}$ and thins $c_{2}\left(r^{*}, \tau, w\right)$ make this problem complex. Nonetheless. the problem can be sulved numerically using standard descent methords. and we denote the solution by $x^{*}(\tau, w)$.

In the diffusion scheme the long run average cost of the entire prohlem is mimimizerl. Given that the optimat cycle center $x^{\circ}\left(\tau, w^{\prime}\right)$ is known. the minimization of efpration 13
$1$

reduces to a diffusion control problem with a drift cont rol ( via $\tau\left(w^{\circ}\right)$ ) and a singular control (via $w_{0}$ ). Let $V\left(u^{\prime}\right)$ be the potential (relative value) function and $g$ be the gain (optimal long run arerage cost). Although the drift of $\mathrm{II}^{\circ}$ is unbounded, we assume that standard arguments apply (see Mandl 1968), and express the associated Hamilton-Jacobi-Bellman optimality equations. after using equation (2), as

$$
\begin{equation*}
\min _{\tau\left(u^{\prime}\right)}\left\{\sum_{i=1}^{N} c_{2}\left(x^{\cdot}\left(\tau, u^{\prime}\right), \tau, w^{\prime}\right)+\frac{K^{\prime}+s l^{\prime \prime}\left(u^{\prime}\right)}{\tau}-g-c^{\prime \prime}\left(w^{\prime}\right)+\frac{\sigma^{2}}{2} l^{\prime \prime}\left(w^{\prime}\right)\right\}=0 \quad \text { for } u^{\prime} \leq u_{0} \tag{23}
\end{equation*}
$$

and

$$
\begin{equation*}
I^{\prime}(w)=0 \quad \text { for } w \geq w_{0} \tag{24}
\end{equation*}
$$

As in MRW, we numerically solve the diffusion control problem by approximating the diffusion process by a Markor chain. This Markor chain approximation algorithm Was developed by Kushner (197万), and we refer readers to Kushner and Dupuis (1992) for details of the algorithm, WRW contains a full description of its application to solving the corresponding optimality equations for the SELSP. Becanse the optimality equations in MRW are very similar to equations (23)-(24). we omit a deseription of the algorithm. and refer readers to Appendix 1.

When there are no setup time's. however, the diffusion process II becomes a RB.II and the diffusion control prohlen is easy to solve. Although the cycle length $\tau$ and cycle center $x^{6}$ must still be optimized for each total workload level. they can be done individually without the need to refer to or update the potential function $l^{\prime \prime}(w)$. Since the steady state distribution of the total workload process $11^{\circ}$ is exponential when setup times are zero. the optimal idling threshold is given by

$$
\begin{equation*}
u_{0}^{*}=\operatorname{argmin}_{w^{\prime}} \int_{u^{\prime}}^{\infty} c(w) \frac{2 c}{\sigma^{2}} e^{-\frac{2}{\sigma^{2}}\left(w-u^{\prime}\right)} d w . \tag{2.5}
\end{equation*}
$$

where $c$ and $\sigma^{2}$ are the parameters for the RBMII .
3.4. Proposed Policy. The solution outlined in $\$ 3.3$ neds to be unscaled to be implemented. Athough the translation to an momomalized police has considerable room for interpretation, we propose an intuitive policy. The heary traflie andysis finds

a minimum leve of work experienced by an individual protuct over the course of a cycle for every total workload level. Because work is depleted while the machine is serving it. We propose that the machine continne production on the current product unt it this minimum amount of work is reached, and then begin setting up for the next product in the cycle. In addition, the machine idles when the total worktoad level has fallen to the idling threshold.

We define the policy in terms of two quantities that are naturally observed in practice: $\dot{O}_{2}(t)$, which is the number of orders of product $i$ in queue for $i=1 \ldots \ldots, N$ and $I_{i}(t)$, which is the number of completed units of product $i$ in finished goods inventory for $i=N^{c}+1 \ldots, \lambda$. For ease of exposition, we let $\dot{I}_{2}(t)=0$ for $i=1, \ldots, N^{c}$. The linear identity $O_{2}-I_{2}=\mu_{2} H_{2}$, where $O_{2}(t)=\bar{O}_{2}(n t) / \sqrt{n}$ and $I_{2}(t)=\dot{I}_{2}(n t) / \sqrt{n}$. which is known to hotel for a wide variety of queueing systems in heary traflic. is used to translate the heary traflic solution to a schertuling policy in terms of $\dot{O}_{2}(t)$ and $\dot{I}_{2}(t)$. The proposed policy is: Switch ont of product $i$ when
$\dot{O}_{2}(t)-\dot{I}_{2}(t) \leq \sqrt{n} \mu_{2}\left[r_{2}^{c} \cdot\left(\frac{\sum_{j=1}^{\lambda} \mu_{j}^{-1}\left(\dot{O}_{j}(t)-\dot{I}_{j}(t)\right)}{\sqrt{n}}\right)-\frac{\tau^{*}\left(\frac{\sum_{j=1}^{v} \mu_{j}^{-1}\left(\dot{O}_{j}(t)-\dot{I}_{j}(t)\right)}{\sqrt{n}}\right) p_{2}\left(1-\rho_{2}\right)}{2}\right]$
and idle the machine when

$$
\begin{equation*}
\sum_{i=1}^{X} \mu_{i}^{-1}\left(\tilde{O}_{2}(t)-\tilde{I}_{2}(t)\right)=\sqrt{n} u_{i j}^{*} . \tag{27}
\end{equation*}
$$

where $x_{0}^{c^{*}}\left(w^{\prime}\right) . T^{*}\left(w^{*}\right)$ and $w_{0}^{*}$ are determined from the optimization procedure ontlined in $\{3.3$. Because a computational proceture is being omployet, we must choose a value of the heary traffic parameter $n$, and we let $n=(1-p)^{-2}$. As in MRW, exploratory computations (not shown here) reveal that the performance of the proposed poliey is very insensitive to onr choice of $n$.

Although we to not do so here. mure complicated policies can he created. At any point in time over the cycle. onr analysis yelets the fluid workload level of each product. This type of information can be used to determine when random events thruw the cyele

## - <br> 0

迤
off course in a manner not predicted by the IITAP's $O(\sqrt{n})$ fluid sating. The dymanic cyclic approach can thus provide "red flags" or warnings for mmsual surges in demand or slow-downs in machine processing. A more complirated policy using this information would specify when to skip products in the cycle or when to jump to a product that has an musually high number of orders. We leave the specification of suclu policies for future investigation.

## 4. DETERMINISTIC DUE-DATE LEAD TIMES

In this section we assume that due-date lead times for each product are deterministic. thereby allowing us to write a closed form expression for the cost per cycle in equation ( 2 ) in §.1.1. In addition, we are able to state a quick method in $\S 4.2$ for determining the optimal cycle center $r^{c^{\circ}}$ and provide a formulaic solution. With this, cycle length $\tau$ is found in terms of $I^{\prime \prime}(w)$ and the total workluad $w$. Howerer, the solution to the diffusion control problem must still be computed by the Marko chain approximation algorithm. The proposed solution is stated in 84.3 . Subsections 4.I and 4.5 are devoted to some structural properties of the optimal solution and the value of due-date lead times. respectively:
4.1 Cost per Cycle. Let each product i have a deterministic due-date lead time of $f_{2}$. which is $f_{2}=f_{i} / \sqrt{n}$ under the fluid scaling. The cumulative distribution function is

$$
F_{2}^{c}(s)=\left\{\begin{array}{ll}
0 & \text { if } s>\bar{f}_{2}  \tag{28}\\
1 & \text { if } s \leq f_{2}
\end{array} .\right.
$$

Fur a given cycte center $x_{i}$. cycle length $\tau$ and tutal workluad level $u_{\text {. }}$. the cost per cerle for a standardized product is given by (19). with, $f_{2}$ in place of $l_{1}$.

To find the cost per cycle for a customized product. We must determine the behavior of $D_{i}(s, t)$. $L_{i}(t)$ and $D_{i}^{V}(n, t)$ given $r_{i}^{c}$ and $\tau$. By Proposition 1 . we have $r_{i}^{s}=\int_{L_{i}(0)}^{\bar{f}_{1}} p_{1} d s$. or $L_{i}(0)=f_{2}-x_{i}^{s} / \rho_{2}$. Therefore. $L_{i}(0)$ has a range of $\left[-\infty, \bar{f}_{2}\right]$, since for rustomized products, $x_{i}^{s}$ is greater than or equal to zero. This makes intuitive sense: The minimum slack must be no larger than $\bar{f}_{2}$ beeanse no orders can arriwe with larger due-date lead

times. From Propositions 1 and '? respectively, we have

$$
D_{2}(s, 0)= \begin{cases}\rho_{2} & \text { if } s \in\left(f_{2}-x_{i}^{s} / \rho_{2}, f_{2}\right)  \tag{29}\\ 0 & \text { otherwise }\end{cases}
$$

and

$$
D_{i}^{V}(s, t)= \begin{cases}0 & \text { if } s \leq f_{2}-x_{i}^{s} / \rho_{2}-t  \tag{30}\\ \rho_{2} & \text { if } \bar{f}_{2}-x_{i}^{s} / \rho_{2}-t \leq s \leq f_{2} \\ 0 & \text { if } f_{2}<s\end{cases}
$$

We can solve for $L_{2}(t)$ by using Proposition 3: For $t \in\left(\tau\left(1-\rho_{2}\right), \tau\right)$.

$$
\begin{equation*}
\bar{L}_{2}(t)=\bar{f}_{2}-x_{2}^{s} / \rho_{2}-\left(1-\rho_{2}\right) \tau+\left(1-\rho_{2}\right)\left(t-\tau\left(1-\rho_{2}\right)\right) / \rho_{2} \tag{31}
\end{equation*}
$$

Because $\left(1-\rho_{2}\right)\left(t-\tau\left(1-\rho_{2}\right)\right) / \rho_{2}-\left(1-\rho_{2}\right) \tau$ is less than or equal to zero. $L_{t}(t)$ is also bounded aboue bur $\bar{f}_{2}$. Note that this function depends on the the decision variable $x_{2}$, via the initial intentury $x_{t}^{s}$.

We can now substitute (31) into equation (11) to calculate the average cost per cycle. Since no orders arrive with due-date lead times $\dot{L}_{2}(t)$ less than $\bar{f}_{2}$ equation (11) can be rewritten as

$$
\begin{equation*}
c_{t}\left(r^{\llcorner }, T,\left(u^{\prime}\right)=\frac{1}{\tau} \int_{\tau\left(1-p_{t}\right)}^{T}\left(b_{2} L_{2}^{-}(t)+h_{2} L_{2}^{+}(t)\right) d t\right. \tag{32}
\end{equation*}
$$

This structure is similar to that in the SELSP case discussed in MRW. The cost per cycle is broken down into three cases depenting on if orders are unty tardy: only early or both during the course of the cycle. If $L_{2}(t)$ is always greater than zero over the course of the cycle (i.e.. if $\rho_{2} f_{2}-x_{2}^{c}>\tau \rho_{2}\left(1-\rho_{2}\right) / 2$ ) then orders are always filled early and so equation (32) implies

$$
\begin{equation*}
c_{2}\left(x^{c}, \tau \cdot u^{c}\right)=\frac{1}{\tau} h_{2} \int_{\left(1-\rho_{1}\right) \tau}^{\tau}\left[\bar{f}_{2}-x_{2}^{s} / \rho_{2}-\left(1-\rho_{2}\right) \tau+\left(1-\rho_{2}\right)\left(t-\tau\left(1-\rho_{2}\right)\right) / \rho_{2}\right] d t \tag{3:3}
\end{equation*}
$$

which simplities to $c_{2}\left(x_{2}^{c}, \tau, w^{\circ}\right)=h_{2} p_{2}\left(\bar{f}_{2}-x_{2} / p_{2}\right)$. This is very similar to the results from IRLIV: The cost per cscle is equal to that in the SELSP with axes shifted be $\rho_{2} f_{2}$. The similarity can be viewed as an application of littlés law. In our notation, the utilization $\rho_{2}$ corresponds to the arrival rate of work and $f_{2}-x_{2}^{c} / p_{2}$ is the average waiting time. and

their product is the number in queue.
Similarly, if orders are always tardy then $L_{2}(t)$ is less than 0 for alt $t \in[0, \tau]$, and the cost is $c_{t}\left(x^{c}, \tau, w^{\prime}\right)=b_{2} \rho_{2}\left[\left(x_{i}^{c} / \rho_{l}\right)-\bar{f}_{i}\right]$. If orders are both early and tardy over the cycle then $L_{2}(t)$ is both positive and negative over the cycle and the average cost per cycle is

$$
\begin{align*}
c_{2}\left(w^{c}, \tau, w^{v}\right)= & b_{2} \rho_{2}\left[\frac{\left(f_{1}-\frac{x_{t}^{c}}{\rho_{t}}\right)^{2}}{2 \tau\left(1-\rho_{t}\right)}-\frac{1}{2}\left(\bar{f}_{i}-\frac{r_{1}^{c}}{\rho_{t}}\right)+\frac{1}{8} \tau\left(1-\rho_{2}\right)\right]  \tag{34}\\
& +h_{2} \rho_{2}\left[\frac{\left(\bar{l}_{1}-\frac{x_{1}^{c}}{\rho_{1}}\right)^{2}}{2 \tau\left(1-\rho_{t}\right)}+\frac{1}{2}\left(\bar{f}_{2}-\frac{x_{i}^{c}}{\rho_{t}}\right)+\frac{1}{8} \tau\left(1-\rho_{2}\right)\right] .
\end{align*}
$$

Again, this reduces to a Little's law version of the SELSP results.
For ease of reference, if the parameters are such that $\rho_{2} f_{2}-x_{2}^{c}>\tau \rho_{2}\left(1-\rho_{2}\right) / 2$. we say that product $i$ is in condition 1. Similarly, we call product $i$ in condition 2 if $0 \in\left[\rho_{2} \bar{f}_{2}-r_{2}^{c} \pm \tau \rho_{2}\left(1-p_{2}\right) / 2\right]$ and in condition 3 if $\rho_{2} \bar{f}_{2}-x_{2}^{c}<-\tau \rho_{2}\left(1-\rho_{2}\right) / \because$. In summary, the average cost per eycle for customized products is

$$
c_{2}\left(x^{c} \cdot \tau, w\right)= \begin{cases}h_{2}\left(p_{1} f_{2}-x_{2}^{c}\right) & \text { for condition 1 }  \tag{35}\\ \left(b_{2}+h_{2}\right) \frac{-\rho_{1}\left(1-\rho_{1}\right)}{8}+\frac{h_{1}-b_{1}}{2}\left(\rho_{2} f_{2}-x_{2}^{c}\right) & \text { for condition 2 } \\ \quad+\frac{h_{1}+h_{2}}{2 \tau_{2}\left(1-\rho_{2}\right)}\left(\rho_{2} \bar{f}_{2}-r_{\imath}^{c}\right)^{2} & \\ -b_{2}\left(\rho_{2} f_{2}-x_{2}^{c}\right) & \text { for condition : }\end{cases}
$$

This leats to a remarkable result: Equations (19) and (35) imply that for the deterministic due-date case the cost structure for customized products and standardized ones are exactly the same. The only difference between the two types is the restriction that for customized products the cycle center $x_{2}^{c}$ camot be less than $\rho_{2}\left(1-\rho_{2}\right) \tau / 2$. Duedates have transformed customized prorlucts into quasi-standardized ones. We discuss the interpretation of this result in 85.7 and $\S 5.9$.
4.2. Optimization. The explicit derivation of average cost per cycle in $\$ 4.1$ allows Ins to make furt her progress in optimizing this system. First. We derive the optimal cyele center and cycle length. and then construct an algorithm for use in the diffision control problem.

Cycle Center. By onr analysis in \& h. the only difference between the optimization

$$
\begin{aligned}
& \text { 为 } \\
& \text { vill } \\
& \text { ar } \\
& +5-2+\cos = \\
& \text { ris }
\end{aligned}
$$

of the cycle center in ( 20 )-( 22 ) and in MRW is the inclusion of the equation ( 22 ) constraints representing the non-negativity restrictions on customized products. In NRW: the solution to the program withont incqualities ( 22 ) was found exactly. For later reference, we call (20)-(21) the "unconstrained" version of ( 20 )-(22) and denote its solution by $x^{c^{\circ} u}$. As discussed in MRW, the form of the cycle center $x^{c^{\bullet} u}$ is broken down into three regions depending on whether the objective function is linear or quadratic in the cheapest product at the point $x^{c^{\bullet} u}$. We wish to find a similar expression for $x^{c^{*}}$ because it is used in determining the optimal cycle length $\tau$.

The major complication in solving (20)-(22) is the bountary conditions in equation (22). We exploit the structure of the objective function to determine the structure of $x_{2}^{c^{*}}$ and to find which $x_{2}^{c^{*}}$ s are binding with respect to the inequality constraints. The objective function is piecemise quadratic with linear edges. It is convex and so if a local minimum exists it will be a global minimum. As per Bertsekas (1995), the Lagrangian associated with (20)-(22) with fixed cycle length $\tau$ and total workload level $w$ is

$$
\begin{equation*}
L\left(x^{v}, \lambda, \mu\right)=c\left(x^{c}, \tau, w^{c}\right)+\lambda\left(\sum_{i=1}^{N} x_{i}^{c}-w^{\prime}\right)+\sum_{j=1}^{N^{c}} \mu_{j}\left(\frac{\tau \rho_{j}\left(1-\rho_{j}\right)}{\ddot{ }}-x_{j}^{c}\right) . \tag{36}
\end{equation*}
$$

The karesh-kuhn-Tucker necessary conditions state that for local minimum $x^{c}$ o there exist Lagrangian muttiptiers $\lambda^{*}$ and $\mu_{j}^{*}$ for $j=1 \ldots \ldots$ V $^{*}$ such that

$$
\begin{align*}
\Gamma_{\mu^{\prime}} L\left(x^{c^{*}} \cdot \lambda^{*} \cdot \mu^{*}\right) & =0  \tag{37}\\
\mu_{j}^{*} & \geq 0 .  \tag{3}\\
\mu_{j}^{*} & =0 \quad \forall j \in \Theta^{*}, \tag{39}
\end{align*}
$$

where $\Theta^{*}$ is the set of non-binding cycle centers; i.e.. products $j$ such that $x_{j}^{c^{*}}>\tau_{p_{3}}(1-$ $\left.p_{3}\right) / 2$. We suppress the dependence of $\Theta^{*}$ on $T$ and $w$ for increased readability: For additional ease of reference, we categorize the binding products by their condition. Whe let $\Theta^{-1}$ be the set of products with binding cycle centers and in condition 1 and $\Theta^{-2}$ be the set of binding products in condition $\because$ (no hinting product can be in condition 3). The products with binting cycle centers are pushed to their limit. in the sense

that no more work ean be performed on these products. Equation (37) implies that $\frac{\theta}{i x_{i}^{c}} c_{2}\left(x^{c^{*}}, \tau, w^{c}\right)+\lambda-\mu_{2}=0$ for $i=1, \ldots N^{c}$ and $\frac{a}{3 x_{i}^{c}} c_{2}\left(x^{c^{*}}, \tau, w^{\prime}\right)+\lambda=0$ for $i=$ $N^{c}+1 \ldots \ldots V^{r}$. Thus, for $i \in \Theta^{*}$ and $i=1 \ldots \ldots v^{c}$, it follows that $\frac{u^{\prime}}{r_{x_{1}^{c}}} r_{2}\left(x^{c^{*}}, \tau, w^{v}\right)+\lambda=0$. Therefore, the Karesh-Kinh-Tucker conditions are the sane for the non-binding cycle centers as for those in problem (20)-(22). This fact implies that the cycle center optimality argmments in MRW hold for the non-binding $\Theta^{*}$ products. There it was shown that all but the cheapest eartiness (minimum $h_{2}$ ) or tardiness (minimum $b_{2}$ ) product are in condition 2. The condition of the cheapest product is used to categorize the total feasible workload into 3 regions: Region 1, where the cheapest product is in condition 1: region II, where the cheapest product is in condition 2; and region III, where the cheapest product is in condition 3 . Here we use the same region teminology to denote when the cycle center and cycle length are such that the cheapest product is in condition 1 . $\underline{2}$ or 3 . Let $\theta_{b}^{*}$ lie the cheapest tardiness cost product in $\Theta^{*}$ and let $\theta_{h}^{*}$ be the cheapest earliness cost product. For ease of motation. let $\theta^{*}$ equal $\theta_{b}^{*}$ if $u^{>}>\sum_{i=1}^{N} \bar{f}_{i}$ and $\theta_{h}^{*}$ otherwise: the index $\theta^{*}$ corresponds to the " $\mathrm{N}^{\text {th }}$ produrt" referred to in MRW". If we let $\hat{u}=u^{*}-\sum_{j \notin \Theta^{*}} T p_{j}\left(1-\rho_{j}\right) / 2$ then the non-binding product $i \in\left\{\Theta \Theta^{*} \backslash \theta^{*}\right\}$ cycle center is
and the cheapest product cycle center is $x_{\dot{\theta}}^{*}=\hat{\mu}-\sum_{i \in \Theta^{*}} x_{i}^{*}$, where, for $i \in\left\{\Theta^{*} \backslash \theta^{*}\right\}$. $\gamma_{1}=\left(\ldots\left(b_{2}-h_{2}\right) / 2-\left(b_{\theta^{*}}-h_{\theta^{*}}\right) / 2 \ldots\right)^{T}, \gamma_{2}=\left(\ldots\left(b_{\theta} \cdot+h_{\theta^{*}}\right) /\left(p_{\theta} \cdot\left(1-p_{\theta^{*}}\right)\right) \ldots\right)^{T}$. the rector $a_{1}=\left(\ldots a_{23} \ldots\right)^{T}$ is defined by

$$
a_{i j}=-\frac{\frac{p_{1}\left(1-p_{i}\right)}{h_{2}+h_{1}} \frac{\rho_{l}\left(1-p_{i}\right)}{h_{j}+h_{j}}}{\sum_{l \in(-)} \cdot \frac{p_{l}\left(1-\rho_{l}\right)}{h_{l}+h_{l}}} \text { for } \quad i \neq j \text {. and }
$$

$$
\begin{equation*}
\Omega_{u k}=\frac{\rho_{l}\left(1-\rho_{l}\right)}{b_{l}+h_{i}} \frac{\sum_{l \in\{\Theta \cdot \} \frac{m_{l}\left(1-p_{l}\right)}{b_{l}+h_{l}}}{\sum_{l \in \Theta \cdot} \cdot \frac{p_{l}\left(1-p_{l}\right)}{b_{l}+h_{t}}} . \tag{42}
\end{equation*}
$$

and finally where $\bar{r}_{i}=p_{2} f_{i}-\tau \alpha_{i} \cdot \hat{j}_{1}-\left(\sum_{j \in \Theta \cdot} \rho_{j} f_{j}-\hat{i}\right) \alpha_{i} \cdot \gamma_{2}$. For $i \in\left\{\Theta^{\times 1} \cup \Theta^{* 2}\right\}$, we have $r_{t}^{c^{*}}=\tau p_{2}\left(1-p_{t}\right) / 2$.

It is important to note that when a product $i$ is binding yet its Lagrangian multiplier $\mu_{2}$ is zero, the inclusion or absence of $i$ in $\Theta^{*}$ does not affect the cycle centers of the other products. This can be seen by setting the borderline product's cycle center as derived from equation (40) equal to $\tau p_{2}\left(1-p_{t}\right) / 2$ and by subsequent algebraic manipulations. In addition, on the border between regions II and I or III the cycle center does not change if using any of the two corresponding expressions in equation (40). We can therefore conclude that the cycle center is a continuous function of the cycle length $\tau$.

With these expressions for the cycle center, we can restate the average cost per cycle in terms of the cycle length $\tau$ and the total workload level $u^{\text {. For }} i \in \Theta^{*} \backslash \theta^{*}$. it is

cycle for the cheapest product is

The products with binding cycle centers can be in condition 1 or in condition $\because$. Thus for $i \in\left\{\Theta^{-1} \cup \Theta^{* 2}\right\}$ the cost per cycle is

$$
c_{i}\left(T, u^{\prime}\right)=\left\{\begin{array}{ll}
h_{1}\left(p_{2} \bar{f}_{2}-\frac{T p_{1}\left(1-p_{1}\right)}{2}\right) & \text { for } l \in \Theta^{-1}  \tag{45}\\
\frac{b_{1}+h_{1}}{2 T p_{1}\left(1-p_{1}\right)}\left(p_{2} \bar{f}_{2}\right)^{2}-b_{2}\left(p_{2} \bar{f}_{2}-\frac{T p_{2}\left(1-p_{1}\right)}{2}\right) & \text { for } i \in \Theta^{-2}
\end{array} .\right.
$$

Cycle Length. (iiven the form of the cost per cycle in terms of $\tau$ and $w$, we can find an expression for the optinal cycle length $\tau$ by differentiating equation (23) with respect to $\tau$ and solving against zero. The optimal cycle length is expressed in terms of basic system parameters, the set of binding products and the effective setup cost per cycle $S=K^{\prime}+s^{\prime \prime}(u)$. Thus, $\Theta^{*}, \Theta^{* 1}$ and $\Theta^{-2}$ are all functions of $S$ and $u$. If we define the constants.

$$
\begin{align*}
& \xi_{1}^{\Theta \cdot}=\sum_{1 \in \Theta \cdot \bullet \backslash \theta^{\cdot}} \frac{\left(h_{2}+h_{2}\right) p_{2}\left(1-p_{2}\right)}{S}-\frac{\rho_{2}\left(1-p_{2}\right)}{2\left(b_{2}+h_{2}\right)}\left(\frac{b_{2}-h_{1}}{2}+h_{\theta \cdot}\right)^{2}  \tag{46}\\
& +\sum_{i \in \Theta^{\bullet} \cdot} \frac{p_{2}\left(1-p_{2}\right)}{2}\left(h_{\theta^{*}}-h_{2}\right)+\sum_{i \in \Theta \cdot{ }^{\bullet}} \frac{p_{2}\left(1-p_{2}\right)}{2}\left(h_{\theta^{*}}+b_{2}\right) . \\
& \xi_{2}^{\Theta}=\sum_{i \in \Theta \cdot 2} \frac{\left(p_{1} \bar{f}_{2}\right)^{2}\left(b_{2}+h_{2}\right)}{2 p_{1}\left(1-p_{2}\right)} .  \tag{17}\\
& \xi_{3}^{\Theta^{\cdot}}=\sum_{i \in \Theta \in \cdot}\left[\frac{\left(b_{2}+h_{i}\right) p_{1}\left(1-p_{2}\right)}{S}+\frac{b_{2}+h_{2}}{2 p_{2}\left(1-p_{2}\right)}\left(a_{i} \hat{j}_{1}\right)^{2}+\frac{h_{2}-b_{2}}{2} a_{i} \hat{\gamma}_{1}\right. \tag{łい}
\end{align*}
$$

$$
\begin{align*}
& \left.+\frac{b_{2}+h_{2}}{2 \rho_{2}\left(1-\rho_{2}\right)}\left(\rho_{2} \gamma_{2}\right)^{2}\left(\sum_{j \notin \Theta \cdot} \frac{\rho_{3}\left(1-\rho_{3}\right)}{\underline{2}}\right)^{2}+\frac{h_{2}-b_{2}}{\ddot{y}} \alpha_{2} \gamma_{2}\left(\sum_{J \notin \Theta \cdot} \frac{\rho_{j}\left(1-\rho_{j}\right)}{\underline{2}}\right)\right] \\
& -\sum_{i \in \Theta^{\bullet 1}} h_{2} \frac{p_{2}\left(1-p_{2}\right)}{2}+\sum_{i \in \Theta{ }^{\circ 2}} b_{i} \frac{p_{2}\left(1-p_{2}\right)}{2} . \\
& \xi_{+}^{\Theta^{*}}=\sum_{i \in \Theta \cdot \Theta^{\cdot}} \frac{b_{i}+h_{i}}{2 \rho_{i}\left(1-\rho_{i}\right)}\left(\alpha_{i} \gamma_{2}\right)^{2}, \quad \text { and }  \tag{19}\\
& \xi_{5}^{\Theta^{*}}=\sum_{2 \in \Theta^{\bullet} \backslash \theta^{*}} \frac{\left(b_{2}+h_{2}\right) p_{2}\left(1-p_{2}\right)}{8}-\frac{p_{2}\left(1-p_{2}\right)}{2\left(b_{2}+h_{2}\right)}\left(\frac{b_{2}-h_{2}}{2}-b_{\theta^{*}}\right)^{2}  \tag{50}\\
& -\sum_{i \in \Theta \cdot 1} \frac{p_{2}\left(1-p_{i}\right)}{2}\left(b_{\theta} \cdot-h_{i}\right)+\sum_{i \in \Theta^{\bullet 2}} \frac{\rho_{2}\left(1-\rho_{i}\right)}{2}\left(b_{i}-b_{\theta^{*}}\right) .
\end{align*}
$$

then the optimal cycle length can be stated as

In order to use the Markov chain approximation algorithnn discussed in $\$ 3.3$. we need to be able to find $\tau^{*}$ and $x^{*}$ for a given $w^{\prime}$ and for varying $I^{\prime \prime}(u)$. Thus, it is necessary to find the set $\Theta^{*}$ of non-binding products as a function of the set up penalty $s^{\prime \prime}=h^{\circ}+s^{\prime \prime}\left(w^{\prime}\right)$ and workload $u$. In the Appendix 2. We construct an algorithm that generates the set of hinding customized products as a function of effective setup cost for each total workloat level. This algorithm allows the cycle length. cyele center and cyele cost to be calculated. This cost can then be fed into the Markov chain approximation algorithn so that $I^{\prime \prime}\left(w^{\prime}\right)$. and hence the proposed policy can be computed.
4.3. Proposed Policy. The mapping from the solution of the diffusion control problem to the proposed policy is the same as in $\} 3.1$. which implements a switching rule for the machine based on $i_{i}$, the current wortuad present in indivitual orders. wia $\dot{O}_{2}(t)-I_{l}(t) \approx \mu_{2} I_{i}(t)$. In the presence of detemmintic due-dates. however. the andysis in $\$ 4.1$ allows ns to create an alternative switehmg rule based on the minimmm slack of each product viat $\dot{l}_{2}(t) \approx p_{2}\left(f_{2}-i_{2}(t)\right)$. This alternative approath might be eanier
to implement in cases where due-date data are more readily arailable than the levels of order quenes and inventories. Markowitz (1996) uses. Monte ('arlo simulation to compare the two altematives. and finds that the approach given in $\S 3.1$ clearty outperforms the minimum slack method, although the discrepancy between the two policies disappears as the length of the due-date lead time grows: see Narkowitz for detaits.
4.4. Structural Properties. Unfortunately, for $s>0,110$ closed form solution to $V^{\prime \prime}\left(w^{\prime}\right)$ appears possible, even if $\Theta^{*}$ is known for all total workload levels. However. it is possible to derive several structural properties about the derivative of the potential function $I^{\prime \prime}\left(w^{\prime}\right)$, which yields some qualitative insight abont the proposed policy: We assume that as $u \rightarrow \infty$ the set of binding variables $\Theta^{*}$ stabilizes; i.e.. there exists a $u^{\prime}$ such that for all $u_{1} \cdot u_{2}>u^{\prime}$, we have $\Theta^{*}\left(u_{1}\right)=\Theta^{*}\left(u_{2}\right)$. This assumption follows naturally from the behavior evident in observations $1-8$ in the Appendix 2, whieh demonstrates how the products smoothly become binding with respect to ${ }^{\prime}$ ' ant $u^{\prime}$. and the fact that there are only a finite mumber of possibilities for $\Theta{ }^{*}$. These structural properties are similar to the ones derived in MRW. Please see Markowitz for details of their proofs.

Property 1. Let the aterage sotup time per cycles be greater than zero. If region II conditions hold as $w \rightarrow x$. then

$$
\begin{equation*}
I^{\prime \prime}\left(u^{\cdot}\right)=\frac{\underline{2} \sqrt{\varepsilon_{3}^{\Theta^{*}} \xi_{1}^{\Theta^{\bullet}}}+\varepsilon_{6}^{\epsilon_{6}^{*}}}{c} u+o\left(w^{\prime}\right) \tag{52}
\end{equation*}
$$

where $\Theta^{*}$ is the set containing the standardized products and the cheapest backorder product (this product could the customized or standardized) and

$$
\begin{equation*}
\xi_{\epsilon_{j}^{\Theta}}^{\cdot}=\frac{\sum_{j \notin \Theta \cdot} \cdot \rho_{J}\left(1-\rho_{j}\right)+\sum_{j \in \Theta \cdot} \cdot\left(h_{j}-b_{j}\right) \frac{p_{j}\left(1-p_{j}\right)}{h_{j}+h_{j}}}{2 \sum_{j \in \Theta \cdot} \frac{p_{j}\left(1-\rho_{j}\right)}{b_{j}+h_{j}}} . \tag{53}
\end{equation*}
$$

If region III ronditions hold as $w \rightarrow \infty$. then

$$
\begin{equation*}
I^{\prime \prime}\left(w^{*}\right)=-\frac{b_{\theta} \cdot}{c} u+o\left(u^{\prime}\right) \tag{.5}
\end{equation*}
$$

Property 2. If the setup cost per cycle $K=0$ and all of the products are standardized. then the policy at the idling threshold $u_{0}$ satisfies the region II conditions if and only if $h_{i}=h_{j}$ for all $i$ and $j$. If this condition holds then

$$
\begin{equation*}
\tau^{*}\left(u_{0}\right)=\sqrt{\xi_{4} / \xi_{3}}\left(\sum_{\imath \in \Theta^{*}} \rho_{l} f_{2}-u_{0}\right) . \tag{5.5}
\end{equation*}
$$

If $h_{2} \neq h_{j}$ for some $i$ and $j$ then the idling threshold satisfies the region I conditions and $\tau^{*}\left(\mu_{0}\right)=0$.
Property 3. If average setup times is greater than zero, region It conditions hold in the limit as $u \rightarrow \infty$ if and only if the tardiness costs of all the standardized products are equal and the cheapest tardiness cost anong the customized products is equal to or greater than the standardized tardiness cost (or if the tardiness cost of all of the customized products are equal and there are no standardized products).

Like their counterparts in MRW, these three properties provide insights into the nature of the optimal cycle length. By Proposition 3. if the tardiness costs of the cheapest customized product and of all the standardized products are equat. then from equation ( 51 ) and Properts I the optimal cycle length $\tau^{*}$ grows linearly for large total workload $w$. If the tardiness custs are nut equal then from Property 1 and equation (51) $T^{*}$ grows as the square root of tutal workload. Property 2 describes the uptimat cycle length near the idling threshold $w_{0}$.

Beyond MRW, these three properties make statements about $\Theta^{*}$. the set of nonbinding product classes. In the limiting case of $u \rightarrow \infty$. the optimal cycle length is growing and eventually causes all but potentially one customized product to become binding. By Property 2 , around the idling threstrold. if $K=0$ and region I conditions hold, then no products are binding. If region II conditions hold of $h>0$. then $\Theta^{*}$ is a priori difficult to describe.
4.5. The Value of Due-date Lead Times. Based on the analysis of the optimal policy, we can comment on how due-date lead times impact the long run average cont. For systems with standardized goods. due-rlates do mot influence the optimal costs. By a quick inspection of the cost per eycle in equation (19). We see that modifications in

due-date lead times are ulfset by a translation of the eyele center. Thus, the optimal cost is not altered by changes in the due-date lead times: we describe the intuition behind this result in §5.6.

The situation for customized products is more complex. The translation of eycle centers influences the costs associated with binding products. As due-date lead times lengthen, the feasible regions for the cycle center $x$ and cyele length $\tau$ grow. thereby allowing for a lower long run average cost. However, for the zero setup time case, we can show that when due-date lead times becone sufficiently large, no products are binding and hence the long run average cost is independent of the due-date lead times. We do this by solving the control problem for the $s=0$ case. both ignoring binding constraints (i.e.. treating each customized good as a sta ndardized one su that $\Theta^{*}=\{1 \ldots \ldots$. . $\}$ ) and setting the due-flate lead times $\bar{f}_{2}$ equal to zero. Let $w_{0}^{0}$ be the optimal idling threshold. If region Il conditions hold at the idling threshold $u_{0}^{0}$ of this no due-date problem and if in the original problem all of the due-date lead times satisfy

$$
\begin{equation*}
p_{2} f_{1} \geq \sqrt{\frac{\mu_{1}+w_{0}^{0} \varepsilon_{4}^{\left\{1 \ldots \ldots v^{v}\right\}}}{\xi_{3}^{\left.\{1 \ldots \ldots)^{\prime}\right\}}}}\left(\alpha_{1} \hat{\gamma}_{1}+\frac{p_{2}\left(1-p_{2}\right)}{2}\right)-u_{0}^{0} \alpha_{2} \hat{\gamma}_{2}, \tag{56}
\end{equation*}
$$

then none of the products will ever be binding. Since the derivative of $x_{2}^{*}-\tau p_{2}\left(1-\rho_{2}\right) / 2$ with respect to total workload $w$ is positive for the $s=0$ case. we need only check that a product class is non-binding at the smallest workload experienced by the policy, which is the idling threshold $u_{0}^{0}$. Equation (56) guarantees this. Therefore. for due-date lead times satisfying (56). the optimal long run average cost remains constant for the same reason as stated in the stamdardized case.

Similarly, if region 1 conditions hold at the iding threshod $u_{0}^{0}$ and if the due-date leadtimes satisfy

$$
\begin{equation*}
p_{2} \bar{f}_{2} \geq \sqrt{\frac{K}{\varepsilon_{1}\{1 \ldots \ldots . \times\}}}\left(\frac{p_{2}\left(1-p_{2}\right)}{b_{1}+h_{2}}\left[\frac{h_{2}-h_{2}}{\underline{g}}+h_{\{1 \ldots \ldots,\}}\right]+\frac{p_{2}\left(1-p_{2}\right)}{\underline{g}}\right) \quad \text { for } i \neq \theta^{-} \tag{5.7}
\end{equation*}
$$

and

$$
\begin{equation*}
\rho_{\theta} \cdot \bar{f}_{\theta^{\prime}} \geq \sqrt{\frac{I \cdot}{c_{1}\{1 \ldots \ldots, . V\}}}\left(\frac{\rho_{\theta} \cdot\left(1-\rho_{\theta \cdot}\right)}{2}+\sum_{i \neq \theta^{\bullet}} \frac{\rho_{l}\left(1-\rho_{2}\right)}{b_{2}+h_{2}}\left[\frac{b_{2}-h_{2}}{\because}+h_{\{\mathbf{I}, \ldots, . v\}}\right]\right)-u_{0}^{0} \tag{.58}
\end{equation*}
$$

then no product will be binding (one only needs to check at the idling threshold for the same reason as in the region II case).

For positive setup times, Property 3 states that as lung as there is a customized product which does not have the cheapest tardiness cost, that product will eventually be binding for high total workload levels. The tonger the due-date lead times the larger the total workload level before the product becomes binding. Although the aterage cycle cost i high for the workload levels where the protuct class is binding, the density associated with these regions diminishes rapidly. We can infer from this that as the duedate lead times increase. eventually the retuction in long run average cost asymptotically approaches the case where all of the products are treated as if they were standardized. Longer due-date lead times achieve diminishing returns for large total workloads.

## 5. DISCUSSION

In this section, we step through each region of the Venn diagram and discuss the relevant literature along with the insights derived from our analysis of the deterministic due-date lead time case: for ease of reference. the subsections below are numbered in the same way as the regions in Figure 1. Because our focus is on the dymamic stochastic versions of these problems. we do mot inctude the vast literature on deterministic or static stochastic scheduling. For each subproblem. We compute and display a typical set of switching curves on the workload plane that characterize the proposed policy in the two-product case. The cost parameters satisfy $h_{1}=2 h_{2}$ and $b_{1}=2 b_{2}$ in each of these examples. Athengh our computations are restricted to the deterministic due-date lead time case. Narkowitz undertakes a partial examination of the cost per cycle for a customized product with miferm due-date lead times, and the mumerical results suggest that the guatitative observations deseribed in this section arry over to the random duedate lead time case.

Figure 3: Customized products, no setups, no due-dates.
5.1. Customized Products, No Setups, No Due-dates. The olter area of Figure 1 corresponds to systems with only customized goods, no setup penalties and no due-dates. These traditional multiclass quenes are the simplest of the systems displayed in the diagram and have been extensively studied. Cox and Smith (1961) were the first to show the optimality of the "cur mbe" (in our notation, the cp index corresponels to the tardiness cost rate b). Which gives priority to the product that. While serviced. removes cost from the system at the highest rate: see Bertsimas and Nino-Mora (1996) for an up-to-date set of references for this scheduling problem.

Our proposed policy is similar in spirit. The policy parameters can be easily determined from §. $^{1: 2}$. The lack of setups forces region If 10 vanish and the cycle length $T$ to be zero. So dur-dates indicates that $f_{2}=0$ for all products. implying that only the region III conditions can apply: Thus for any total workload $w>0$, the cycle center $x$, is set to zero for all i not ecpual to $\theta_{b}^{*}$. and the cycle eenter for the cheapest backorder product is set to $w$. In this special case. one can trivially calculate that the idling threshold $u_{0}$ is zero. The implied dymamic cyclic policy is then simple in form (see Figure 3 for a two-product example where $b_{1}>b_{2}$ ): Service all but the least expensive product to exhaustion and wwith out of producing the cheapest protuct if there are any higher cost products present. This policy can be interpreted as a two-tevel prionty ruke: All hout the teast expensive product hase high priority and are semed to exhanstion in a cyedic manner: the least expensive product has low priority:

It is worth noting that in the heary traffic limit the equene length of the high priority products vanish and only the lowest priority product is present (see Whitt 1971). It follows that the heaw traflic limiting behavior of the proposed policy is identical to that of a strict "b" priority policy: In both cases. the workload process lies along the $\theta_{b}^{*}$ axis. Thus, in the heary traffic setting nothing is lost between our proposed dymamic cyclic policy and the ch rule.
5.2 Standardized Products, No Setups, No Due-dates. Nulticlass rfueveing systems with standardized proflucts are generally considered to be more difficult to analye than systems with customized products because of the nonlinear cost structure introduced by having both holding and backorder costs. Additionally: when constructing policies for these production/inventory systems. there are no natural switching boundaries as with exhausting a quene in customized systems. These ubstacles have hindered the analysis of even the simplest case: Standardized products with no setups and no due-dates. Zheng and Zipkin (1990) analyze the intuitively appealing longest queue (or smallest fimished goods inventory) policy for a two-product system, which is optimal when both products have itlentical cust parameters and operate under independent base stork policies. Ha (1993) partially characterizes (in terms of switching curves) the optimal policy for the Markovian two-prodnct case. Wein (1992) uses heavy traffic theory to develop a dynamic priority policy and an aggregate base stock policy for the multiproduct problem, and Veatchand Wein (1993) expand upon this bexamining index policies in a Darkovian setting and by analyzing the lost sales case. Finally. Pena and Zipkin (1993) propose a policy that combines the best aspects of the policies in Zheng and Zipkin. Ha. and Wein.

Our proposed policy is similar to that of Wein, and readers are referred there for a more in-depth discussion of the basic insights gained from the heaty traflic analysis of this system. From the calculations involving setup penalties and cycle length in \& f.2. T is again zero for this case and only regions I and HI are possible. The eycle center of all
 $u<0$. Beeduse there are no setup times. the total workload process. which measures the total work in backenders minus the total work in linished goods inventory is a Rl3al amel

Figure 4: Standarelized products. no setups, uo due-dates.
the idling threshold $u_{0}$ is negative (i.e.. - $u_{0}$ represent.s an aggregate base stock level for the total work in finished goods inventory) and has an explicit form (see equation (T6) of Wein). The dymamir cyclic policy can be stated as a two-level priority system for mufilled orders with the added complication of a mechanism to build up a finished goods inventory: It has the following rules: l) service all orders with finished goods inventory if available: 2) all (quened orders for products of her than protuct $\theta_{b}^{*}$ have priority and are serviced in an exhaustive cyctic mamer: 3) orders for the cheapest backorder product $\theta_{b}$ : have the lowest prionty: f) if no orders are present and the total workload is above the idling thereshold. then produce product $\theta_{h}^{*}$. Which is the cheapest to hold in inventory. A typical two-product policy (where $b_{1}>b_{2}, h_{1}>h_{2}$ ) is pictured in Figure 1 and, as in the customizet case, the strict priority rule between the products causes the switching curves to nearly overlap on pruduct 2 's axis. The performance of the resulting policy is. in the heary traffic limit. identical to the one suggested by Wein.

Comparing the custonized product and standardized prowluct cases. we see from the proposed policy a distinct role for inventory: It hedges against the risk of hackordering. According to the lITAP. uncertainty in production and demand have their greateat impact on the total workload in the system, ant the time scale decomposition allows the
machine to flexibly address requests for high cost products withont the need for storing the products themselves. Thus, inventory acts as a reservoir of reserve caparity: able to absorb random fluctuations in service and demand. and the proposed policy stores this capacity in the most economical manner possible: It is placed in the cheapest holding cost product. Similarly, when the finished goods inventory is exhansted, the proposed policy is still able to flexibly service requests for high cost prorlucts by neglecting the cheapest backorder product, effectively storing deficit inventory in its cheapest form.
5.3. Customized Products, Setups, No Due-dates. The models represented by region 3 in the Vemn diagram are known as polling systems in the literature on computer communication networks. Althongh considerable research has appeared on the performance analysis of these systems (e.g.. Boxma and Takagi. 1992), the dynamic scheduling of the se multiclass queues with setups have not yielded to an exact analysis. Hofri and Ross (1987). Lin. Nain and Towsley (1992) and hooke (1994) derive structural results. Reiman and Wein (1991) use heary traffic analysis to develop policies for the two-prochuct prohlem. Boxma. Levy and Westrate (199-1) and Bertsimas and Xiu (1993) compute static policies (i.e., polling tables). Browne and l'echiali (1989) derive a quasidynamic index policy to choose sequences of products to service at the start of each cycle. and Duenyas and Van Oyen (1995, 1990) develop scheduling heuristics based on myopic reward rates for systems with setup times and costs. respectively: readers are referred to the literature review of Reiman and Wein (1994) for more detaits.

Our proposed policy is a multiprotuct version of Reiman and Wein's (1991) policy: As in the previous customized case. the lack of due-dates and of standard goods limits the cycle center and cycle length equations to the region 111 formulations. Given that $f_{2}$ equals zero for all $i$, all but the cheapest product. $\theta_{b}^{*}$. is binding and so $\Theta^{*} \subset\left\{\theta_{b}^{*}\right\}$ for all $S$ and all $u$. Thus. the policy can be stated as follows: Service each prothot in a cyelic manner. When set up for all but the cheapest backorder protuct. service it to exhanstion. When set up for $\theta_{6}^{*}$ work on it until its normalized workload reaches
 there are only twe protucts. the policy is itemtical to Reiman and Wein's (1991).

The presence of setups eliminates the two-level prionty sheme seen in the previons

Figure 5: C'ustomized products, setups. no due-dates.
no setup cases because a strict priority rute leads to excessive setups. The proposed policy avoids this by keeping to the cycle. yet minimizes cost by offering quick delivery to high cost prontucts at the pussible neglect of the $\theta_{b}^{*}$ product. However. as in the presious two subproblems, the heave tralfic andysis essentially treats all but the lowest priority product in a similar fashion. These results suggest that for heavily loaded polling systems. it is more herneficial to focus on noncyelic exhanstive policies than dynamic nonexhanstive policies.

A typical two-product policy is shown in Figure ;. The presence of setup penalties has added breadth to the switching curves of Figure 3. The policy can be viewed as not only balancing setups and queneing costs. as directly seen in the formulation of $\tau$ and $x^{c}$. but also as controlling the randomness of the system by isolating the effects of total work fluctuation in the least cost product. This is seen in Figure. j by the huge range of low cost product queue length values (atong the vertical axis) caused by the Huctuation of total workload in the system sersus the relatively confined range of the more expensive prochuct (along the horizontal axis).
5.4. Standardized Products, Setups, No Due-dates. Standardized goods with setups and without due-dates has long been considered the prototype for modeling make-to-stock manufarturing systems. The deterministic version of this problem. which is called the Economie Lot Scheduling Problem (ELSP). Was origimally formutated in 1915 (see Elmaghatoy 1976) ant only recently has the stochastic version of this prothem

44,5 $\cdots-1-\cdots+$ -
 24 (2)

 $\square$

Figure 6: Standardized products, setups. no due-dates.
(the SELSP) receised attention. Graves (1980) develops a heuristic using a Aharkov decision model. Leachman and (iascon (1988). Gallego (1990) and Bourland and Yano (1995) develop heurist ic lot-sizing algorithms that are rooted in the deterministic ELSP. Sharifnia, Caramanis and (iershwin (1991) use a hierarchical decomposition approach to analvze a stochastic fluid version of the problem, Federgruen and Natalan (1995b, 1996) use polling theory to analyze the performance of (periodic and cyclic, respectively) base stock policies for the SELSP, Qin and Loulou (199.5) numerically compute the optimal solution to the two-product problem by modeling it as a semi- hlarkov decision process. Ampindi and Tayur ( 199.1 ) develop a simulation based appruach to compute cost-effective base stock policies, MRW analyze the problem using the HTAP, and Son and Muckstadt (1995) formulate the problem as a stochastic program. and propose a decomposition procedure to solve it.

Our proposed policy restrieted to standardized goots and no due-dates reduces to that of MRIV. Since all of the protucts are standardized, there are no orthant constraints and hence no binding products: i.e.. $\Theta^{*}=\{1 \ldots \ldots . \backslash\}$. At three regions are possible and The eycle length. cycle center and idting threshold are nontrivial. I sample policy is
pictured in Figure 6.
A detailed deseription of the proposed policy for the SELSP and a summary of the key insights are given in MRIW. Here we briefly cover the highlights as they pertain to the larger problem. As in the standardized goods, no setup case, the policy treats the total workload inventory as a reservir of stored capacity: used to hedge against demand and service rate uncertainty. The switching curves are constructed so that excess inventory is stored in the cheapest holding cost product $\theta_{h}^{*}$. and deficit inventory is moved into the cheapest backorder product $\theta_{b}^{*}$. Positive inventory also serves a secondary role: A small cache of inventory impedes backordering on an individual product level while the machine is producing other products during a cycle. The amount of inventory required is dependent on the length of the cycle, which is an increasing function of the setup penalty as shown in equation (51). Also. setups introduce breadtla between the switching curves. as seen in comparing Figures 4 and 6 .
5.5 Customized Products, No Setups, Due-dates. The systems in region 5 of Figure 1 reflect manufacturing facilities that service custoner reguests on a make-to-order basis with the additional feature that customers do not want the goods immediately but at some future time. The inclusion of due-dates causes an explosion in the dimension of the state space. which makes this problem difficult. Pandelis and Teneketzis consider earliness and tardiness penalties and examine properties of an optimal policy: Righter uses stochastic ordering to further characterize aspects of an optimal policy: Van Mieghem (199.5) studies a multiclass queneing system with costs based upon a convex nondecreasing function of each order's delay in the system. I'sing heary traflic analysis. he shows that a generalized $c \mu$ rule is asymptotically optimal. where $c$ is a dynamic function that represents each job"s marginal cost of delay.

As in both no setup. no due-date cases. the lack of setup penalty causes the cycle length $T$ and region 11 to vanish. The presence of (deterministic) due-dates however. moves the switching curves into the orthant so that they lie on a new set of axes: i.e.. by equation ( 10 ) the cycle centers $x_{i}^{c}$ are shifted by $\mu_{2} f_{i}$. The proposed poliey can be described as follows: If the total work in unfinished orders is less than $\sum_{i=1}^{i} p_{2} f_{i}$, thent orders that are almost at their che-date have prionity and are serviced in a cedic mamer.

Figure 7 : ('ustomized products, no setups, due-dates.
and if there are no urders near their due-dete and the total workload level is above the idling threshold, then the machine works on orders for the product with the smallest earliness cost. If the tutal workload is greater than $\sum_{i=1}^{v} p_{2} f_{i}$ then all prothets other than the cheapest tardiness product $\theta_{b}^{*}$ have priority and their orders are serviced in a cyclic manner just as their hue-tates are reached or passed; the cheapest tardiness product $\theta_{b}^{*}$ has kowest priority and its orders are serviced only when the due-dates of the higher priority goods are distant.

A two-product example is given in Figure 7. As in the no due-date, no setup examples. the switching curses fur the two products nearly overlap. However, the switching curve shift onto the new due-date axes is readily transparent by comparing Figures 4 and 7 . The shift of the due-date axes in the worktoad plane represents the toterance of the policy toward aging orders not the in the near future. The region corresponding to the "northeast" portion of the plane corresponds to the workload states where there is too much work and orders are completed past their due-date. The "sonthwest" portion of the plane is an area where orders are few and if worked on will be completed early: The intersection of the new axes (the reetical one is hidden behind the switching curve) corresponds to the state where the wait in quene for an order exactly equals its due-date lead-time.

As in the previous sulproblems, the proponed policy minimizes the costs of the higher cust products at the expense of the cherapest product. The policy attempts io service the

high cost products in such a manner that they are completed exactly when they are due. As in the no due-date case. excess urders are shifted to the cheapest tardiness product $\theta_{b}^{*}$. The presence of due-dates allows the scheduler to atoid tardiness costs by staying "ahead of schedule" - that is. by completing some of the orders early to allow for more slack when there is an unexpected surge in demand or difficulty in production. It hedges against this unertainty in the most economical manmer possible: It only completes earty those products with the cheapest earliness cost. However, customized products have a limit on how much "deficit" workload they can hold: The policy is forced to switch setup when a product is exhausted of orders, and. as in the "kink" on the horizontal orthant boundary in the proposed switching curves in Figure 7 . further hedging against tardiness must be achicred by completing earty the nore expensive product. In addition. given that the low total workload is costly, the idling threshold may be nonzero so as to avoid states with high earliness costs.

It is interesting to compare these results to those of Vall Mieghem. His cost structure can accommotate a multiclass queuming system with custumized products. no setups and deterministic due-dates, where the earliness costs $h_{2}$ are set to zero for all products. In this case. Van Mieghem's generalized che mule gives priority to tardy urders over early orders (and early ones can be processed in any manner), and priority within the tardy group is determined. in out notation, by the highest "b" rule". Aso. the server works as long as there are orders waiting.

Our results previde the dynamic cyedic rersion of this policy just as was seen ith the standardized and customized cases with no due-dates and no setups. There is a two-level priority scheme for tardy orders. where all but the cheapest tadiness cost product $\theta_{b}$ have priority and are serviced cyclically; tardy $\theta_{b}^{*}$ orders are serviced only when there are no other orders past due. Since all of the carliness costs are equal. the proposed policy. services the orders to exhanstion when there are no tardy orders. The idling threshold is set at zero and so dues not contribute to the poliey: The machine works as long an there is work to do. Igain. as in the previous cases withont setups, the dymame cyclic policy has the same hehavior as the generatized of rute in the heary traflic limit. Thus. our policy and \an Mheghem"s are simitar when they are both restricted to the one ease

Figure $x:$ Standardized products. no setups, due-dates.
where the models overtap.
5.6. Standardized Products, No Setups, Due-dates. This case, which has not been explicitly studied to on knowledge, is similar to the customized case. but without the orthant boundaries. The cycle tength and region II vanish. The cycle centers are shifted unto the new due-date axes $p_{i} f_{2}$. The presence of a finished goods inventory: however, modilies the proposed policy from the previons customized one. The policy can bee interpreted as the following rules: 1) only fill orders when they are due either from the finished goorts inventory or directly from the machine out put: : 2 ) if the total workloarl present in orders mimus that in finished goods inventory is atrove $\sum_{1} p_{2} f_{2}$ then follow a two-level priority scheme: Orders for high tardiness cost goods (i.e... all but $\theta_{b}^{*}$ ) that are closer to their due-date have prionity and are serviced in a ryclic manner and tardy $0_{b}^{*}$ orders have lower priority: 3 ) if total work is helow $\sum_{2} p_{2} f_{2}$ then tardy orders have prionity and are serviced cyclically, and if there are no tardy orders the machine works on the lowest holding cost product $\theta_{h}^{*}$ and stores them in the finished goork inventors: matil the workload idting threshokd is reached. A typical wo-prodnct poticy is depicted in Figure S .

This polioy is exactly the same as a shifted standardized. no setmpe no the-date
policy: Moreover, in the heary traffic limit both systems incur exactly the same long run average cost. This perhaps surprising result makes int nitive sense upon closer inspection. The due-dates we have considered have a special structure: They are $O(\sqrt{n})$ and so only influence the fluid limit. This implies that in our policy, orders will arrive becone late and be serviced before the total workload has an opportunity to significantly change. Moreover. the orders are continuonsly arriving and in this time frame the machine is not able to either get ahead or fall behind on orders. Thus, if we are servicing orders that are due today and arrived 10 days ago, then tomorrow we will be servicing orders due tomorrow that arrived mine days ago. Due-date lead times have not provided any additional flexibility to the system; orders are not serviced earlier or later than usual. only the absolute time of service has been shitted.

The difference between this case and the customizel one is the ability to pre-make goods for a finished goods imentory. With stantardized goods, the policy is always allowed to hedge against backordering by investing in stored work in its cheapest form. In the customized case (see Figure 7), the inability to manufacture goods in anticipation of future orders means that the policy might be forced to store work in a more expensive product when it rums out of orders for $\theta_{h}^{*}$ products and so mmst finish early the next cheapest holding cost product.

In a system not in heave traflic, however, the long run average cust is affected by the due-date lead time. Buzacott and Shanthikmar (1993, §-5) find the long run average cost for the single-product Narkovian version of this problem. If one optimizes over the idling threshold (Buzacott and Shanthikumar's target level), then the long run average cost is

$$
\begin{equation*}
\frac{h}{\ln \rho} \ln \left(\frac{h}{b+h}\right)+h \tilde{f}\left(\mu \frac{1-\rho}{\ln \rho}+\lambda\right) \tag{.59}
\end{equation*}
$$

as long as the due-date lead time $\tilde{f}$ is less than or equal to $\frac{1}{\mu(1-\rho)} \ln \left(\frac{h+b}{h}\right)-w_{0}$ (this condition guarantees that the idling thereshold $u_{0}$ is nompositive). The first tem in (59) is equal to the long run areage cost for a system without due-dates and the secoud is the due-date contribution. Since $\mu \frac{1-\rho}{\ln \rho}+\lambda$ is always negative. due-date lead times reduce the cost of the system.

The reason for the diflerence between the heavy traflic system and the nuseated one can be most easily moderstood bex examining the unsealed system with no orders and a full inventory: When an order arrives, the total order workload increases above the idling threshold and the server initiates production. Goods can be tinished before the order is due, inflating the inventory level beyond the heavy traffic prediction. This has two effects: Ifolding costs are greater and the chance of backordering is decreased. The duedate leadtime has allowed the system to hedge against backordering, something that the heary traffic approximation has not allowed for. Nonetheless, as utilization grows close to one, the long run average cost in (59) is dominated by $\frac{h}{\ln \rho} \ln _{\mathrm{n}} \frac{h}{b+h}$, which is independent of the due-date lead time.

It is also interesting to mote the difference between our system and the inventory model of Hariharan anel Zipkin (1995). They consider a facility that employs ane-for-one replenishment scheme for a single product, and optimize the on-site inventory level. There is a detemninistic due-date lead time. La for recpuests and a lead time for the facility's orders, $L_{s}$. Ther find that increasing the due-date lead time decreases the average cost of the system up until the due-date lead tine equals the re-order lead time: when $L_{d} \geq L_{s}$ further increases in the due-date leart time have no value. One might be tempted to conclude that the two results are consistent, because $L_{d} \geq L_{s}$ for our system. However. in our problem. The sojourn time for orders phays the role of $L_{s}$, and it is also $O(\sqrt{n})$ he the heary tratfic conditions: hence. $L_{d} \geq L_{\text {s }}$ does not atways hold in our system. We believe the reason for the difference between Harilaran and Zipkin's result and ours is that Hariharan and Zipkin consider an uncapacitated system, where inventory hedges against demand uncertainty hut loes not act as stored workload, freeing machine resources for higher cost products. With longer due-date lead times there is less urgency for orders to be replenished quickly and so less inventory is needed on-site to hedge against backordering. In contrast. in our capacitated model. the same amount of stered work is needed independent of dhe-date lead time. as discussed above.
5.7. Customized Products, Setups, Due-dates. Wie know of no previous work analytically treating this problem. This case contams all of the complexity of $\%$. 2 . . It three regions can be present. cyele lenght cyele center and idfing threshold are nontrivial

Figure 9: ('ustomized products, setups. long due-rlates.
and products can be binding. It is interesting to note that if the due-date lead times are long enough (Figure 9), the proposed policy tooks like a shifted set of SELSP switching curves (systems with setup times, however. will always be slightly different because the cxpanding cycle length $\tau$ will eventually hit the orthant boundary for large total workfoad. by Property I in 8t.1). If the due-dates are short (Figure 10), the switching curves bump into the orthant and flatten out. Readers should note that Figures 9 and 10 are based on cases with setup costs but no setup times, whereas the other cases with setups in this section contain setup times but no setup costs. In addition to viewing the case as a shifter SELSP policy, it ran also be thought of as the customized product, no setups. due-dates case (Figure i) with breadth added to the switching curves as was seen in the transformation between the no due-date cases without setups to the case with setups (Figures 3 and $\overline{\text { a }}$ ).
5.8. Standardized Products, Setups, Due-dates. This subproblem corresponds to the center of Figure 1. and has received very little attention. The switeh to standardized products from the customized case eliminates the orthant boundaries. thereby simplifying the nature of the optimal dymamie rydic potios: The poliey is merely the SELSF

Figure 10: ('ustomized products. setups, short due-dates.
policy on the shifted set of dur-date axes (see the example in Figure 11 and compare it to Figure 6): moreover, as in s.5. the cost under the optimal dynamic cyctic policy is insensitive to due-date lead times. Markowitz performs simulation runs for the $\rho=0.9$ case that support this insensitivity conjecture.

It is worth noting that as duc-date lead times increase, the entire set of switching curves passes into the positive orthant. Hence. longer due-date lead times can iransform a make-to-stock methorl of servieing demand for standardized goods into a make-tu-order method. When due-date learl times reach this critical level. it is optimal to fill orders early and incur holding costs: these early orders provile a bufler against backordering as would a finished goods inventory:
5.9 Systems with Customized and Standardized Products. Lastly. we consider mixed systems with both customized and standardized products, which wonld correspond to the border of the "Standardized" vircle in Figure 1. Our distinction between customized and standardized is based entirely on product design, and the derived switching curves distate which standardized products are made-to-order. In contrast. other work tras treated the partition of constomized and standardizen goorls as a decision to be

Figure 11: Standardized products. setups. due-dates.
optimized. For example. ('arr ot al. (1993) consider a queneing system with no setups or due-dates, where the make-to-order (IITO) goods represent low demand items that have priority over the make-tu-stock ( MTS ) ones. This intrinsic priority rule allows fur a performance analysis of the MTO /MTS partition but does not involve optimal scherduling of the products. Nguyen (1995a) performs a heavy traffic andysis of mixed systems without setups or due-dates, and with lost sales instead of backordering. In a sulsequent paper (1995), she examines different priority rules for the MTO and MTS products and suggests an algorithm for setting base stock levels. Felergruen and Katalan (199.5a) examine mixed systems with setups and no due-dates, and compare several priority mules for switching from MTS goods to MTO. They also propose a heuristic for partitioning MTO and MTS items.

Finally, there is the full problem: ('ustomized and standardized products. setups and due-dates. All of the previons cases are sulsets of this general model. It is the proper setting to ask questions of balancing inventory costs and setup penalties, of setting base stork inventory levels and avoiding backondering. of determining due-date lead time effects and natural due-date-hased partitions of WTS/MTO goods. Yet. this gemerality

Figure lö: Mixed products, setups. due-dates.
does not complicate the system beyond the previons cases. The product mix is accounted for in our calculations by the presence of orthant constraints on some products and not on others (see Figure 12 for an example of a mixed system with one customized product. one staidardized product, setup times and due-dates). Most of the insights described carlier about the interactions of setups. due-dates and orthant constraints carry over directly to the combined system.

## 6. COMPUTATIONAL STUDY

Computational results in Reiman and Wein (1991) and MRW confirm the accuracy and robustness of the IIT IP for make-to-order and make-to-stock systems, respectively: with either setup costs or setup times. but no due-dates. Here we report on a computational study that tests one methods with respeet to mixed systems and due-dates. Unfortumately: the presence of due-dates prevents an exact derivation (via dymanie pro gramming) of the optimal policy and an exact evaluation of the varions policies muter consideration. Therefore. we employ dismete exent simulation for these tasks. For sim-

plicity, we only examine two-product systens with deterministic duc-date lead times. Interarrival times. service times and setup times are independent and exponentialty distributed. The service is preemp'ive-resmme and there are no setup costs. For all of the scenarios in this section, we start with systems void of both orders and inventory and then perform ten independent runs. Each run contains a 100.000 time unit initialization period and statistics are reconded for the next 10.000 .000 time units.

We wish to examine three issues for mixed systems: The accuracy of the heavy traffic approximation. the effectiveness of our proposed policy, and the value of increased duedate lead times. The first product is customized and the second is standardized. Using the same parameters as a case in MRW, we set the earliness costs to $h_{1}=2, h_{2}=1$. tardiness costs to $b_{2}=5 h_{1}$. service rates $\mu_{2}=1$, arrival rates $\lambda_{1}=0.6 . \lambda_{2}=0.3$ and average setup time per cycle $:=20$. We set the due-date lead times $f_{1}=f_{2}$ and test $f_{2}$ for ratues equal to 0. 20 and 100 .

Straw Policjes, Since we do not have a convenient point of reference provided by an optimal polics, we compare the proposed policy, which is defined in equations (26)$(27)$. to three straw policies. The first straw policy is the proposed policy without duedate considerations: that is. the policy in (26)-(2T) is calculated with the duc-date lead time $f_{2}$ set to zero. The second straw pulicy is a hybrid base stock/exhaustive poliey where the customized prodnct is serviced to exhanstion and the standardized product is produced up to a base stock level $\mu^{-1}$ e. which is equivalent to a $-\dot{i}$ order workload level. The base stuck level is calculated in a fashion analogous to the standardized, no due-date case in $\S 3.1$ of MRWW. as follows. The cyele center for the customized product (product 1 ) is set to $\tau(w) p_{1}\left(1-p_{1}\right) / 2$. The cycle center for the standardized product is set to $\tau\left(w^{\prime}\right)_{p_{2}}\left(1-p_{2}\right) / 2+i$. If we define $r=i / \sqrt{n}$, then the cycle length is $\tau(w)=$ $2(u-v) /\left[p_{1}\left(1-p_{1}\right)+\beta_{2}\left(1-\beta_{2}\right)\right]$. Lnder this polies, the totat normatized workhoad II has a stationary gamma density with parameters $\alpha=2 \sqrt{n}(1-\rho) / \sigma^{2}$ and $3=s \sum_{i=1}^{2} p_{2}(1-$ $\left.\rho_{2}\right) / \sigma^{2}($ see ('offman, Puhatskii and Reman 199.51$)$ ). The aserage cost for this policy is
N"
given by

$$
\begin{align*}
& \int_{-v}\left(c_{1}\left(\frac{u-v}{\rho_{1}\left(1-\rho_{1}\right) \sum_{i=1}^{2} \rho_{t}\left(1-\rho_{t}\right)}, 2 \frac{u-v^{*}}{\sum_{t=1}^{2} \rho_{t}\left(1-\rho_{t}\right)} \cdot u^{\prime}\right)\right. \tag{60}
\end{align*}
$$

We set $n$ equal to $(1-\rho)^{-2}$ and use a steepest descent algorithm to find the parameter 1. which minimizes (60).

The third straw policy is again a hybrid base stock/exhaustive policy where the base stock level is determined by an exhaustive search using multiple simulation rums (the results of which are not shown here). These two hybrid policies. which will be referred tu as the hybrid HTAP policy and the hyrid coarch policy, together offer the opportunity to determine the accuracy of the HTAP. Numerical results are contaned in Table I and switching curves for the herbel search policy and the proposed policy are given in Figures 1:3 and If for the $f_{2}=0$ and $f_{2}=100$ cases. respectively:

| Due-bate <br> Lead Time | Cost of Hybrid HTA1 | Cost of Hybrid Seareh | Cost of I'roposed w/o D-data | Cost of Proposed Policy |
| :---: | :---: | :---: | :---: | :---: |
| 0 | 290.3 (土 3.2) | 290.0 ( $\pm 2.7)$ | $274.6( \pm 1.9)$ | $2 \mathrm{~T} 1.6( \pm 1.9)$ |
| 20 | $201 . h( \pm 2.7)$ | 199.5 ( $\pm 3.2)$ | 186.3 ( $\pm 2.1)$ | 181.1 ( $\pm .2 .7)$ |
| 100 | 122.R ( $\pm 1.1)$ | $121.3( \pm 1.3)$ | $158.3( \pm 0.9)$ | $109.7( \pm 1.1)$ |

Table 1: Simulation results for the mixed system.

Obsertations: Straw Policies. The long rum aserage cost for both hybrid policies decreases with longer due-date lead times. With zero dut-date lead times, orders for the high cost customized product are immediately hackordered. driving up costs. As the duedate lead times increase. orders for the customized product are less tardy and costs fall. However, one would expect that eventually they would start to increase again (under the hybrid policies) as the due-date lead times become inordinately long and loulding costs become excessive.

The two hybrid policies incur nearly identiral costs. The base stock levels for the search policy are 4.5, 37 and $1: 3$ for the $f_{2}=0.20$ and 100 casses. respectively and the corresponding HTAP levels are 39. 2s and ; Athongh the base stock levels for the

MTS Hybrid Poliey

due-date axis

Figure 13: Switching curves for a mixed system with zero due-date lead times.
search policy are consistently higher than those of the HTAP policy, the act wal difference in long run average cost is very small. For the hybrid exhaustive/hase stock policy, the long run average cost as a function of base stock level appears to liave a shallow slope abont the optimal solution, ant the heary traffic analysis is able to identify a base stock level that performs quite well.

Finally: it is not surprising that the performance of the proposed policy that assumes zero due-date lead times deteriorates as due-date leal times increase. This deterioration suggests that it is not advisable to ignore due-dates when due-date lead times are large.

Obsentions: Proposed Policy: For the reasuns cited above the proposed policy also has decreasing long run average costs as due-date lead times increase. The proposed policy has an important ardantage over the hylurd policies that can be seen in Figures $1: 3-$ 1t: It is able to avoid large buildups of product 1 orders. botlı in queue and wating to be shipped. The cost reduction achieved in Table I by the proposed policy relative to the hytrid policies is in the $5-10 \%$ range. and increases with the due-date lead time $f_{2}$. For the $f_{i}=0$ casce the proposed policy avoids severe backordering by switching to product

Figure 14: Switching curses for a mixed system with due-date lead times of 100 .

1 if there is an excessive mumber of orders in quente. However. due to the severity of the setup penalty: the cycle tength $\tau$ is long and so the product 1 buildup must be large Thus, the marginal benefit of the proposed policy over the hybrid policy is not great in this case. As the due-date lead time increases, however, the proposed policy has a greater opportunity to avoid excessive product 1 costs. The rycle length $T$ is still large but the policy is able to attain a balance between earliness and tardiness costs by cycle center placement. As seen in Figure 14 . the amount of product 1 workload is maintained near the due-date axis $\rho_{1} f_{1}$. Which is the level of product 1 workload necessary for a new order to wait in quene for an amount of time exactly equal to its due-date lead time. The hybrid policies are not able to perform this type of cost minimization.

The Value of Dut-date Lead Times. As due-date lead times increase our heary traffie analysis (see $\xi$ f. (i) predicts that the long rum aremage costs under the mixed system shomble decrease until the duc-date leal times hit a mitioal value: beromel this threshold value.
 almost equal to the cont muder the corremponding SELSP'. Noreover. heeanse the hatrid

policies optimize the standardized and customized products independently, the inventory costs for the standardized product should be independent of the due-date lead time under these policies.

For the hybrid policies. there is little change in the costs the to the standardized product in Table l: Its average holding and backorder costs remain approximately 23 and 1. respectively, for all values of the due-date lead time, and atmost all of the savings are due to the customized product. In contrast, the inventory custs for the standardized product in the proposed policy change with the due-date lead tine (in the $\tilde{f}_{2}=20$ case the earliness cost is 16.7 and the tardiness cost is 12.7; in the $\tilde{f}_{i}=100$ case, they are 34.7 and 16.2 , respectively). This difference is due to the dymamic nature of the proposed policy: Unlike the hey rid polieies, the proposed polin: is able to shift inventory costs between the two prorlucts by changing the eycle center and cycke length for each workload level.

To analyze the costs incurred bey the customized products. we compare the mixed system to its corresponding SELSP' Which is MRW"s asymmetric. setup time. $b_{1}=10$ case. According to the dynamic programming results in row 13 of Table VIII of NHWH: the SELSP cost under the dynamic cyctic policy is 106.5 . which is fairly similar to the cost of 109.7 incurred in the mixed system in Table I when $f_{2}=100$. This snall cost discrepancy suggests that the critical due-date lead time threshold for this problem is less than $f_{2}=100$. Unfortunately: it is very difficult to calculate the critical threshold due-date lead time for the optimal policy when setup times are present.

An alternative comparison where we can catculate the threshold value is te contrast the mixed system under the hyrid search policy with the SELSP under the generalized base stock policy described in 83.1 of MRWI. The generalized base stock policy is similat in form to the hyrrid IITAP policy. except it inclules a nontrivial idfing threshold not present in the hybrid policy. By our analysis in $\S$ I. 1 . the threshold due-date lead time is $n_{1} / p_{1}$. where $v_{1}$ is the base stuck level from the SELSP ease. For this SELSP seenario. on was found to be 19.0 . making the eritical due-date lead time $f_{1}$. equal to ix. 6 . Hemere heary traffic theory predicts that the mixed system cost of $f:=100$ shombl be roughty equal to the SELSP cost. Referring again to row 1.3 of Table $11 / 1$ of IHRIS. We find that the SLBLSP cust mater the generalized base stuck peliey is 117.0 . As we predicted. this

value is reasonably close to the mixed system cost of 122.8 in Table I, particularly since part of this discrepancy is probably due to the increased sophistication of the generalized base stock policy relative to the hybrid HTAP polic:

## 7. CONCLUDING REMARKS

Theories for scheduling a manufacturing facility have examined the issues of customizedstandardized product mix. setup penalties and due-dates. but have typically focused on each of them separately: In this paper, Coffman, Pulalskii and Reman's heavy traffic averaging principle is used to investigate the composite problem. With it, we outline a computational methorl to optimize within the class of dynamic eyclic policies. For the case where each product has its own deterministic due-date lead time, we qualitatively describe the policy: Our methodology particularly the detemmation of how due-dates affect the behavior of the flum system. may be useful for studying other systems with delay constraints. such as due-date schertuling problems arising in computer applications. inventory-routing problems with time windows, and inventory management of perishable products.

Our heary traffic andysis suggests that the risks inherent in the uncertainty of random demand and servire processes camot be removed. Yet. by proper scheduling, the impact of the variability can be reduced by channeling the thuctuations in order quenes and finished goods inventories into low cost regions of the state space. The presence of setups, due-dates and product mix each dictate how this dampening of cost is performed. Our results yiek a simple interpretation of how these facets affect the switching curves that characterize the proposed policy:

$$
\begin{aligned}
\text { due-dates } & =\text { shifts } \\
\text { setups } & =\text { breadth } \\
\text { customized/standardized goods } & =\text { presence/absence of orthant boundaries. }
\end{aligned}
$$

The simplicity of the lirst of these three observations - that deterministic due-dates merely. shift the optimal switching curves - is particularly striking. given how notorionsty diflicult it is to analyze due-date scheduling problems in a drmamic sochastic sotting. Thin three-point guide allows us to gualitatively moterstand the matme of fymanic stoclaantic

scheduling problems with deterministic due-dato learl times without explicitly calculating the solution.

Our analysis also sheds light on the vatue of foreknowledge of customer demand (iun the form of due-datess when the system is heavily loaded. and how this information affects the optimal pulicy: We find that the costs incurred by standardized products are independent of the due-date lead times for these products. When due-date lead times increase beyond a certain level, the standardized products are made-to-order, but there is no change in cost: orders are filled before their due-date, and these early orders play the same role as a finished goods inventory: They provide a buffer against backordering. Although costs for customized products initially decrease as due-date lead times increase, when the (deterministic) due-date lead tin es reach a critical value the costs level off and the customized product incurs nearly the same cost as standardized products. In essence. large due-date lear times blur the make-to-order/make-to-stock distinction: Thes cause standardized products to the made-tu-order and provide customized products with the flexibility to be produced carly. thereby imitating a make-to-stock mode of production.

## ACKNOWLEDGMENT

This research was supported be a grant from the Leaders for Wamufacturing Program at MIT and NSF grant DIM-905re9t. We thank Marty Reiman for helpful comments and thank Frank Kelly for sharing with us an early draft of Aldous. Kelly and Lehozsky (1995). which deepened our understanding of the problem.

## APPENDIX 1: THE MARKOV CHAIN APPROXIMATION ALGORITHM

This supplement descritses the Markov chain approximation algorithm that selves equations (23)-(24). The Markor chain is created by discretizing the one dimensional total workload state space into intervals of size $h$ and time into blocks of size $\Delta t^{h}$. If we define $Q^{h}=\sigma^{2}+|c h-s|$ then the transition probatilities of the Markor chain are

$$
\begin{equation*}
P^{h}(u \cdot u-h)=\frac{\sigma^{2}+2 h\left(\frac{s}{\tau(u \cdot)}-c\right)^{+}}{2 Q^{h}} \tag{i1}
\end{equation*}
$$

$$
\begin{equation*}
P^{h}(u, u+h)=\frac{\sigma^{2}+2 h\left(\frac{s}{\tau(u)}-c\right)^{-}}{2 Q^{h}} \tag{62}
\end{equation*}
$$

and

$$
\begin{equation*}
P^{h}\left(w_{0} \cdot u^{\prime}\right)=1-\frac{\left(\sigma^{2}+h\left|c-\frac{s}{\tau(u)}\right|\right)}{Q^{h}} . \tag{63}
\end{equation*}
$$

and the time interval itself additionally must be set to

$$
\begin{equation*}
\Delta t^{h}=\frac{h^{2}}{Q^{h}} . \tag{6+t}
\end{equation*}
$$

There is one exception: The reflection boundary is never reached and so the transition probability in the feasible region before $w_{0}$ is

$$
\begin{equation*}
\dot{p}^{h}\left(w_{0}+h \cdot w_{0}+h\right)=1-p^{h}\left(w_{0}-h \cdot w_{0}-2 h\right) . \tag{6.3}
\end{equation*}
$$

Ath the of her transitions have zero probabilities.
We can now write the dyamic programming optimality equations as

$$
\begin{equation*}
I(w)=\sum_{y} \tilde{p}^{h}(u \cdot y) I(y)+\left(c\left(w^{\cdot} \cdot \tau \cdot w\right)-g\right) \Delta t^{h} . \tag{66}
\end{equation*}
$$

Becanse the Markor chain is a birth-death process. for a policy $\tau$ and $w_{0}$ the steady-state distribution and gain can be easily catculated from the transition probabilities. Similarly: the potential function can be recursively calcutated by

$$
\begin{equation*}
I(w+h)=\frac{u-c\left(w^{c} \cdot \tau(u) \cdot w\right)+\left(1-\tilde{P}^{h}(w \cdot w)\right)!(w)-\tilde{P}^{h}(u \cdot u+h)!(w+h)}{\tilde{p}^{h}(w \cdot u-h)} \tag{6i7}
\end{equation*}
$$

With I $\left(w^{\prime}\right)$ and $g$ determined. an improvement iteration on $\tau$ can be arhieved by performing the optimization embedted in equation (23) and an improvement on wo finding the threshold that minmizes the gain g. The algorithm terminates when $\tau$ and wo converge.

## APPENDIX 2: AN ALGORITHM FOR $\Theta^{*}(s)$

This appendix deseribes an algorithm that constructs $\Theta^{\circ}(S)$ by finding an intial set

U14
introduce the notation specifying the dependence of the set -$)^{*}$ of non-binding protuct: on $S$. Our task is complicated by two facts: As increases the optimal solution can jump in region, and there is me guarantee that when a protuct becomes binding and leaves $\Theta^{*}\left(s^{\prime}\right)$ it does not re-enter for larger $s^{\prime}$. We simplify our calculations of $\Theta^{*}\left(s^{\prime}\right)$ by including the type of region the cycle center and cyche length imply in our accounting. Let $\Theta^{-}\left(s^{\prime}\right)$ denote $\Theta^{*}\left(s^{\prime}\right)$ when the cycle center and cycle length satisfy the region 1 conditions. $\Theta^{* / L}(S)$ for the region If conditions and $\left.\Theta\right)^{* / I}(S)$ for the third region. The algorithm is based on the following eight observations (proufs are provided in Appendix: 3):

1. The cycle center $x^{c^{\circ}}$ and cycle length $T$ are continuous functions of the effective setup cost per crcle i'.
2. The optimal cycle length $\tau$ is monotonically increasing with respect to it.
3. If protuct, is not in $\Theta^{*}$, then for $\Theta^{\prime}=\Theta^{*} \cup\{i\}$ the eycle center $x^{\prime \prime}$ and circle length $T^{\prime}$ calculated with $\Theta^{\prime}$ satiofly $x_{2}^{\prime \prime}<T^{\prime} p_{2}\left(1-p_{2}\right) / 2.2$.
4. If $5^{\prime \prime}$ and $5^{\prime \prime \prime}$ are such that $.^{\prime \prime}<5^{\prime \prime \prime}$ and both their respective optimal cycle lengthe and cecle centers satisfy region I (III) conditions, then $\Theta^{* I}\left(S^{\prime \prime}\right) \subset \Theta^{* I}\left(S^{\prime}\right)\left(\Theta^{* I I}\left(S^{\prime \prime}\right) \subset\right.$ $\left.\Theta^{* l l}\left(S^{\prime \prime}\right)\right)$.
5. If $s$ is such that the optimal cycle length and cecle centers imply a shift from region II to region $I(I I I)$, then $\left(\Theta^{-I}\left(\lim _{\epsilon \rightarrow 0} \dot{S}^{\prime}+\epsilon\right)=\Theta^{-I I}\left(\lim _{c \rightarrow 0} b^{\prime}-\epsilon\right)\left(\Theta^{-I I I}\left(\lim _{t \rightarrow 0} S^{\prime}+\epsilon\right)=\right.\right.$ $\left.\Theta^{\cdot I I}\left(\lim _{\rightarrow \rightarrow 0} S-\epsilon\right)\right)$.
6. If $S^{\prime}$ and $S^{\prime \prime \prime}$ are such that $S^{\prime \prime}<S^{\prime \prime \prime}$ and both their respective optimal cycle lengths ant cycle centers satisfy region $I I$ conditions. then $\Theta^{* I I}\left(S^{\prime \prime}\right) \subset \Theta^{* I I}\left(S^{\prime}\right)$.
7. When a condition I binding product i changes to condition?. it remains binding.
8. If $S$ is such that the optimal cycle length and crole centers imply a shift from region I or $I I I$ to region $I I$. then $\Theta^{* / I}\left(\lim _{\epsilon \rightarrow 0} x^{\prime}+\epsilon\right)$ can be calculated br an iterative algorithm.

With these eight olmervations. the algorithm we suggest is simple. From an intial $\Theta^{* I}(0), \Theta^{* I I}(0)$ and ()$^{-I I I}(0)$. we track how each evolves as $s$ is increased. Three types of events can change $-\Theta^{*}\left(\right.$ S' $\left.^{\prime}\right)$ : A shift in region. a mon-hinding customized preduct can berome binding and a condition I binding protuct can become condition 2. (iven equations (10)

and (51). We can calculate the range of is before any one of these events occur.
The initial set of non-binding products is chosen as follows. For an effective setup cost of zero. cycle length $\tau$ becomes zero as region 11 vanishes. If the total worktoad level $w$ is less than $\sum_{i=1}^{N} p_{i} f_{i}$, then there are few orders remaining in the system and it may be advantageons to make binding some of the cheaper customized products. Let $\left\{\epsilon_{1}, c_{2}, \ldots,{ }^{\prime}, v\right\}$ be an arliness ordering of the products such that $h_{e_{1}} \leq h_{1_{2}} \leq \cdots \leq h_{e, v}$. We find $\Theta^{* 1}(0)$ by removing products one-by-one. A product $t$, is removed if it is next in the $\epsilon_{i}$ list, is customizable and is insufficient for storing the remaining work, i.e. $\sum_{i=1}^{J} \rho_{2} f_{2}<\sum_{i=1}^{v} \rho_{2} f_{i}-u^{.}$. The process stops when either a standardized product is reached in the $t_{2}$ list or the next product $\epsilon_{3}$ implies $\sum_{i=1}^{j} p_{i} f_{2}>\sum_{i=1}^{\lambda} \rho_{2} f_{i}-\mathbb{N}$. If $\mathbb{u}$ is greater than $\sum_{i=1}^{X} p_{i} f_{2}$, then $\Theta^{-I}(0)$ is set to $\{\ldots . .1$ ' $\}$. Both $\Theta^{-11}(0)$ and $\Theta^{-I / I}(0)$ are always set to $\{1 \ldots, 1\}$.

Given an intial $\Theta^{*}(0)$ we can find the range of effective setup costs before the set changes. The set changes when the minimum such that one of the three events occur: A shift in region, the binding of a customized product or the change in condtition of a binding product. For a given $G^{\prime \prime}$ with non-binding set $\Theta^{*}\left(S^{\prime \prime}\right)$ a region change occurs when

$$
8
$$

$$
=0
$$

$$
\text { ther }+\frac{1}{1}+x^{2}
$$

$$
-p^{2}-\pi_{4}
$$

$$
{ }^{2}+x^{2}+x^{2}
$$

$$
\frac{1}{4}
$$

where

$$
\begin{align*}
& -\sum_{2 \notin \Theta^{*}\left(S^{\prime}\right)} \frac{p_{2}\left(1-\rho_{2}\right)}{2} \\
& \Xi_{2}=\sum_{i \in\left\{\Theta \cdot / / /\left(S^{\prime}\right) \backslash \theta_{b}^{*}\left(S^{\prime}\right)\right\}} \frac{\rho_{t}\left(1-\rho_{t}\right)}{b_{i}+h_{z}}\left[\frac{b_{2}-h_{t}}{\mathscr{2}}-b_{\theta_{\theta^{*}}\left(S^{\prime}\right)}\right]-\frac{\rho_{\theta_{b}^{*}\left(S^{\prime}\right)}\left(1-\rho_{\left.\theta_{b}^{*}\left(S^{\prime}\right)\right)}^{2}\right.}{2}  \tag{70}\\
& -\sum_{i ⿻^{( } \Theta \cdot{ }^{\circ / 1}\left(S^{\prime}\right)} \frac{p_{2}\left(1-p_{i}\right)}{2} .
\end{align*}
$$

A customized product becomes binding when

$$
\text { U- }=\text {, }
$$

Lastly, product 1 changes from condition 1 to condition 2 when

Thus the current set of $\Theta^{*}\left(S^{\prime \prime}\right)$. $\Theta^{* 1}\left(S^{\prime \prime}\right)$ and $\Theta^{* 2}\left(s^{\prime \prime}\right)$ is valid for effective setup cost from $S^{\prime}$ to the minimum $S^{\prime}$ greater than $S^{\prime \prime}$ in equations (68). (71), (72). At that point. $\Theta^{* I}(S), \Theta^{* I I}\left(S^{\prime}\right)$ and $\Theta^{* I I I}\left(S^{\prime}\right)$ are updated according to observations $\overline{5}$ through s and the process is repeated. The algorithmends when either all customized productes are binding or all but one of the customized products are binding and the cheapest is the condition 3 product in region $H I$ with $\frac{1}{1 T}\left(x_{i}-\frac{t p_{1}\left(1-\rho_{2}\right)}{2}\right)<0$ (in the other regions, increasing cycle length impies that either the customized product would become binding or that the region would eventuatly shift).

## APPENDIX 3: PROOFS OF EIGHT OBSERVATIONS

In this supplement we prove the eight observations stated in Appendix 2 .
Observation 1. For a given $w^{\prime}$ and $1^{\prime \prime}\left(w^{\prime}\right)$, the quantity in equation (23) is continnons with contimuns derivatives with respect to the cyche length $\tau(\tau \geqslant 0)$. eyele center $r$ and effective setup cost per cycte $s$. In addition, the boundary conditions are also contimuns with continuons derivatives with respect to $x^{c}$. $\tau$ and $S$. Thus, the Karesh-Kulm-Tucker necessary optimality conditions change contimously with $s$. The only way the optimal $x^{c^{\circ}}$ and $\tau^{*}$ contd be discontinuous with respect to an increase in $S$ is if there were multiple optimal solutions for a given $S$ and $\overrightarrow{ }$. This is not the case since the objective function is convex with respect to eycle center and cycle length and has the unigue opt imal sohtion presented in equations (10) and ( 51 ).

Observation $?^{2}$. This is easily seen from ergation (inl) and the first observation implying the contimuty of $\tau^{*}$ during changes of himding products $\left(\theta^{*}\right.$ and changes in region.

Observation 3. This fotlows from the const ruction of $\Theta$ *.
Observation 1. We show this be indueting on the cheapest products. ('onsider the
region I rase: let 0 h be the first cheapest product to becomebinding in region I at effective setup cost $s^{1}$ with cycle length $\tau^{1}$. All other products with smaller earliness costs must be binding in condition ?. The instant product $\theta_{h}^{l}$ becomes binding. the cycle center has reached the pusitivity homblary and so

$$
\begin{equation*}
w-\sum_{i \in \Theta^{* 2}\left(S^{1}\right)} \frac{\tau^{1} p_{2}\left(1-p_{2}\right)}{2}-\sum_{i \in \Theta \cdot{ }^{1}\left(S^{1}\right) \backslash \theta_{h}^{1}}\left[p_{2} f_{2}-\frac{\tau^{1} p_{2}\left(1-p_{2}\right)}{2} \frac{b_{2}-h_{2}+2 h_{\theta_{h}^{1}}}{b_{t}+h_{t}}\right]-\frac{\tau^{1} p_{\theta_{h}^{2}}\left(1-p_{\theta_{h}^{1}}\right)}{2}=0 . \tag{7:3}
\end{equation*}
$$

In order for the minimum work experienced uver the cycle. $x_{i}^{c}-\tau p_{2}\left(1-p_{2}\right) / 2$. to reach the boundary as $\tau$ is increased. its derivative must be negative; that is.

As $\begin{aligned} & \text { increases. } T \text { also increases, and hence the cheaper binding condition " prothets can }\end{aligned}$ only re-enter in condition 2 and will not re-enter in region 1 . dilditional products might leave $\Theta^{-I}\left(S^{1}\right)$ but since $\frac{h_{1}-h_{1}+2 h_{h}}{h_{1}+h_{2}}<1$. equation ( $7-1$ ) witl become more negative. This implies that equation ( $7: 3$ ) will remain negative for larger $\tau$. and so $\theta_{h}^{1}$ cannot re-enter $\Theta^{* 1}$. The $i^{\text {th }}$ induction on the cheapest proctuct results in an argument identical to the previous one where equations ( $7: 3$ ) and ( 1.1 ) are modified by replacing $\theta_{h}^{\prime}$ with $\theta_{h}^{\prime}$ and $c^{1}$ with $5^{2}$.

The other nore expensibe prorlucts that become binding in region I also cannot re-enter $\Theta^{-1}$. Since $h_{\theta_{h}\left(s^{\prime \prime}\right)}>h_{\theta_{h}\left(s^{\prime}\right)}$, from the above intuction we have

$$
\begin{equation*}
\frac{p_{2}\left(1-p_{2}\right)}{2} \frac{b_{2}-h_{1}+2+h_{\theta_{h}^{*}\left(s^{\prime}\right)}}{b_{2}+h_{2}}<\frac{p_{2}\left(1-p_{2}\right)}{2} \frac{h_{1}-h_{1}+2+h_{\theta_{h}^{*}\left(s^{\prime \prime}\right)}}{b_{2}+h_{2}} . \tag{i}
\end{equation*}
$$

Therefore. the cycle center of the more expensive non-binding products are tower for larger s. Since cycle tength $T$ increases with $S$. if the cycle center becomes lens than Tpor $\left(1-p_{2}\right) / 2$. and hence binding, it will remain binding.

The same argument holds for region 11 l .
Observation 5. Since cycle centers and excle lemgth are contimuons in s. Whis is

after a transition to region I. Binding condition I products must have become buding in region 1 and remain binding be obsersation 1 (in region HI, a condition 1 product becoming non-binding would violate the region III definition). (ondition - products in region 1 will have a cycle center of the form $\rho_{2} \bar{f}_{2}-T \alpha_{2} \cdot \hat{\rho}_{1}-\left(\sum_{J \in \Theta \cdot} \cdot \rho_{J} \bar{f}_{j}-u^{\prime}\right) \alpha_{2} \cdot \gamma_{2}$ and so the derivative of $r_{2}-\tau \rho_{2}\left(1-p_{2}\right) / 2$ with respect to $\tau$ is always negative. This implies that a condition 2 binding cycle center will contimue to push against the orthant boundary:

Observation 6. We prove this by examining $x_{2}^{c}-\tau p_{2}\left(1-\rho_{2}\right) / 2$. the derivative of the minimum amount of work over the course of a cycle, with respect to $\tau$. Once the derivative is negative, we show that it remains so as further products are removed from $\Theta^{-I I}$. Thus when a product becomes binding at $x_{2}^{c}-\tau \rho_{2}\left(1-\rho_{2}\right) / 2=0$. as $\tau$ expands it cannot re-enter: The negative derivative would continue to push the cycle center against the orthant boundary: Since no binding products in $\Theta^{* I I}(S)$ can become non-binding in the ot her regions by ubservation $\therefore \Theta^{-l l}(G)$ is a nonincreasing set with $S$.

The derivative of minimum workload in region II for a non-binding product is

$$
\begin{align*}
& =-\frac{\frac{p_{1}\left(1-p_{2}\right)}{\left.2_{1}+h_{j}\right)}}{\underline{\Sigma}}\left[\sum_{j \in \rightarrow \cdot I_{()}}\left(2 b_{2}+h_{j}-b_{j}\right) \frac{p_{j}\left(1-p_{j}\right)}{b_{j}+h_{j}}+\sum_{j \notin \rightarrow \cdot{ }^{I /}(s)} p_{j}\left(1-p_{j}\right)\right] . \tag{76}
\end{align*}
$$

where $\Sigma=\sum_{j \in \in \cdot H(b)} \rho_{j}\left(1-\rho_{j}\right) /\left(b_{j}+h_{j}\right)$. Therefore the derivative is negative if and only if

$$
\begin{equation*}
\sum_{j \in\left(\in \cdot I^{I}(S)\right.}\left(2 b_{2}+h_{j}-b_{j}\right) \frac{p_{j}\left(1-p_{j}\right)}{b_{j}+h_{j}}+\sum_{j \notin \in \rightarrow \cdot I_{(S)}(S)} \rho_{j}\left(1-p_{j}\right)>0 . \tag{7}
\end{equation*}
$$

Thus, at effective setup cost.$^{\prime \prime}$. if the derivative of product $i$ is negative and a more expensive tardiness product / leaves to form $\Theta^{* H}\left(\varsigma^{\prime \prime}\right)$. then equation (iT) implies
which is

$$
\begin{equation*}
\sum_{J \in \Theta^{* I I}(S)}\left(\underline{2} b_{2}+h_{j}-b_{j} \frac{p_{j}\left(1-p_{j}\right)}{b_{j}+h_{j}}+\sum_{j \notin \Theta^{* I I}(S)} p_{j}\left(1-p_{j}\right)+2_{p_{l}(1)}-p_{l} \frac{b_{2}-b_{l}}{b_{l}+h_{l}}>0 .\right. \tag{79}
\end{equation*}
$$

Since $b_{t}-b_{l}<0$, we have

$$
\sum_{j \in \Theta^{\cdot l /}(S)}\left(2 b_{2}+h_{j}-b_{j}\right) \frac{\rho_{J}\left(1-\rho_{j}\right)}{b_{j}+h_{j}}+\sum_{j \neq(-)^{11}(S)} \rho_{j}\left(1-p_{J}\right)>0
$$

and so the derivative remains negative. If a cheaper tartiness protuct I leaves forming $\Theta^{* I I}(S)$, the derivative of the cheaper product implies

$$
\begin{equation*}
\sum_{j \in \Theta \cdot I_{(S)}(S) \cup\{l\}}\left(2 b_{l}+h_{j}-b_{j}\right) \frac{p_{j}\left(1-\rho_{j}\right)}{b_{j}+h_{j}}+\sum_{j \notin \Theta \cdot I_{T(S) \cup\{b\}}} p_{j}\left(1-p_{j}\right)>0 . \tag{S1}
\end{equation*}
$$

The left side of (81) is lese than

$$
\sum_{J \in \in \cdot \rightarrow \cdot I_{(S)}}\left(2 b_{2}+h_{j}-b_{j}\right) \frac{\rho_{j}\left(1-\rho_{j}\right)}{b_{3}+h_{j}}+\sum_{J \notin \Theta \cdot{ }^{I I}(S)} p_{J}\left(1-p_{j}\right)
$$

because their difference is

$$
\sum_{1 \in \in \cdot H_{( }(s)} 2\left(b_{2}-b_{l}\right) \frac{p_{1}\left(1-p_{j}\right)}{b_{j}+h_{j}}
$$

Therefore the derivative of the minimum worktoad ower a cocle for product i remains negative after / becomes binding.

Observation 7 . If this change occurs in regions 1 or $l l$. then product i remains binding because in these regions the quantity $\frac{\partial}{d T}\left(x_{1}-\frac{T p_{2}\left(1-p_{2}\right)}{2}\right)$ is always negative for a condition 2 product. If the change occurs in region 1 . a condition 1 product in region If implies that

$$
\begin{equation*}
\sum_{j \in \leftrightarrow \rightarrow \cdot\left[I_{(S) \backslash\{,\}}\right.} \frac{p_{j}\left(1-p_{j}\right)}{2\left(b_{j}+h_{j}\right)}\left[b_{j}-h_{j}+2 h_{2}\right]-\frac{p_{2}\left(1-p_{2}\right)}{2}<0 . \tag{ㄴ}
\end{equation*}
$$

or

$$
\begin{equation*}
p_{2}\left(1-p_{2}\right)+\sum_{j \in \in \cdot \rightarrow l_{\{-\infty \backslash\{2\}}} \frac{p_{j}\left(1-p_{j}\right)}{b_{j}+h_{j}}\left[h_{j}-b_{1}-2 h_{2}\right]<0 . \tag{4.7}
\end{equation*}
$$

Subtracting equation (72) from equation (8.1) we get

$$
\begin{equation*}
\sum_{j \in(\Theta) \cdot} 2\left(b_{2}+h_{2}\right) \frac{\rho_{j}\left(1-p_{j}\right)}{b_{j}+h_{j}} . \tag{86}
\end{equation*}
$$

Which is positive. As stated in ohservation 6 , this implies that $\frac{1}{4 \tau}\left(x_{2}-\frac{\tau p_{4}\left(1-p_{2}\right)}{2}\right)$ is negative.
Observation 8 . A conclusion from the previous seven observations is that $\Theta^{*}\left(S^{\prime}\right)$ is relatively predictable with the notable exception of transitions from regions I and III to region II. At these transitions, binding products may again enter $\Theta^{*}(S)$. Re-calculation of $\Theta^{* I I}(S)$, however, is not difficult. At the effective setup cost $S^{\prime}$ point of transition from region I or III to region II, all binding products not before in $\Theta^{-I I}\left(S^{\prime \prime}\right)$ for $S^{\prime \prime}<S^{\prime}$ should be re-included in $(-)^{-11}\left(S^{\prime}\right)$. The crole center can then be re-catculated. Those products such that either their cyele centers are infeasible or were previously binding and currently have a negative cycle center derivative (as determined by equation (7i)) can be removed from $\Theta^{* I I}\left(S^{\prime}\right)$. By observation (6. they do no re-enter. This process can be repeated until $\Theta^{-1 I}(S)$ is found such that all bimfing products with negative minimum workload per cecle derivatives are removed. Whe resulting $\Theta^{* / I}(S)$ is equal to $\Theta^{* I I}\left(S^{+}\right)$.
