Abstract—Cognitive Radio built on top of spectrum sensing is promised to provide more capacity for users wherever and whenever needed and improve radio spectrum utilization in clever and fair manner. However, practical spectrum sensors have to be implemented and they should provide sufficient protection to legacy users of radio spectrum. This leads to trade-offs between primary user protection ratio, device form factor, cost and power consumption. In this research we have derived requirements for antenna efficiency, sensitivity and linearity of practical spectrum sensors. These are verified by field measurements using spectrum sensor embedded to a mobile phone.

Keywords; cognitive radio, spectrum sensing, mobile phone, white space devices, digital television; DVB; UHF; intermodulation

I. INTRODUCTION

Cognitive radio network has two ultimate goals to address [1]: *First, to provide highly reliable communication for all users of the network, wherever and whenever needed. Second, facilitate efficient utilization of the radio spectrum in a fair-minded and cost-effective manner.* Spectrum sensing is key enabler for cognitive radio, allowing every device access to unutilized resource, when and where it is available and needed. However, legacy devices have to be given special rights to radio spectrum when it is justified and well reasoned. For this Federal Communications Commission (FCC) has set rules in the United States of America [2].

In order to protect legacy or primary devices two basic approaches have been presented: geo location database [3] and spectrum sensing. First method needs reliable location of the device and access to the database. Basically there are two different types of devices using the database: fixed devices, like Wi-Fi access points, establishing CR networks and mobile devices, joining available networks. Devices that either do not have connection to the database or exact geo location information are the problem. In first phase of secondary spectrum usage, database based method will be dominant. However, spectrum sensing has several advantages why more research is requested [4].

Initial approach in primary user protection using spectrum sensing was to set fixed, easy to certificate

measure: sensitivity. Requirement was set to -114 dBm in 6 MHz bandwidth. Sensitivity requirement provides an easy way to limit interference level of primary users. Developed spectrum sensing algorithms have been shown to fulfill initial FCC requirements for sensitivity. This problem has two edges: too high primary protection ratio reduces available capacity for secondary usage. Even current sensitivity requirement makes spectrum sensors very hard to implement with state-of-the-art radio front-ends and antennas, especially in small form-factors and power consumption.

Presented CR demonstrators with spectrum sensor use either lab grade measurement instruments with high price, high power consumption, and large form factor, or they does not provide sufficient linearity to avoid problems with strong interfering signals [5]-[8].

Sensitivity of small cheap commercial embedded devices is affected by antenna issues. Spectrum sensor prototype with built-in UHF antenna is described in companion paper [9]. It shows that lower end of TV band suffers from small antennas in mobile phone sized devices. There is also a trade-off between sensitivity and dynamic range of spectrum sensors, especially with wide-band systems [10]. We show by field measurements that either we have to accept severe capacity loss because limited linearity of practical spectrum sensors or we have to develop scheme to relax sensitivity requirement of single sensor. Collaborative sensing via topographical spectrum map provides interesting alternative for calculated geo location database.

II. SPECTRUM SENSOR PROTOTYPE

Used spectrum sensor prototype is implemented on Nokia N900 mobile computer [9]. It has following custom parts: built in UHF antenna, UHF receiver, and FFT-based cyclostationary feature detector on FPGA [11]. Needed controls and information gathering mechanics are implemented as SW processes. Gathered information consists of band, channel, received signal strength estimate, feature detector statistics value, date and time, and GPS location if available. Measurement data is collected into database, implemented either on device or into a server on the Internet.

This research is supported by Tekes (the Finnish Funding Agency for Technology and Innovation).

System performance is presented with details on [9]. Key parameters are shown in TABLE I.

TABLE I. SPECTRUM SENSOR PROTOTYPE PERFORMANCE

Frequency range	570 – 850 MHz
Bandwidth	8 MHz
NF	4 dB
IIP3	-11 dBm
Antenna efficiency	-14 – (-7) dB
Detection time	460 ms
Sensitivity, Pdet = 0.9	-118 dBm
False alarm rate	0.01

III. FIELD MEASUREMENTS

Two sets of field tests were carried out in capital area in Finland. First measurement set was done mostly outdoors in urban Ruoholahti area in Helsinki. Two sensors were used, both using internal antennas. The measurement set consists of spectral samples from 37 different locations, shown in Fig. 1. One spectral sample includes detection time, GPS location, band, channel, received signal strength in dBm and DVB-T detection statistics from UHF channels 34 to 60 (578 – 784 MHz). Detection time was set to 460 ms and detection statistics positive detection threshold to produce constant false alarm rate of 1%. Measured signal strengths are shown in Fig. 2. Corresponding estimated probabilities of DVB-T detections on different channels are shown in Fig. 3. There is DVB-H repeater in the area, detected on channel 35. Espoo TV transmitter is transmitting on channels 32, 35, 44, 46, and 53.

TABLE II. DVB-T TRANSMITTER PARAMETERS.

DVB-T transmitters	Esboo	Tallinn
Latitude:	60.1778	59.4713
Longitude:	24.6403	24.8875
Mast heighth:	313 m	272 m
Transmission power:	47 dBm	42 dBm
Occupied channels	32, 35, 44, 46, 53	45, 59, 64

TV transmissions on measurement range are detected with high probability. Channel 59 is occupied by Tallinn TV transmitter on average 78 km away. Open source Splat! [12] radio propagation calculation tool, using Longley-Rice Irregular Terrain Model [13] and NASA SRTM-3 Version 2 Elevation Models [14], was used for field strength estimation. Used transmitter parameters are shown in TABLE II., receiver was assumed to be 3m above sea surface. Estimated field strength, shown in Fig. 4, in Ruoholahti area is 20-60 dB μ V/m. Field strength has large variation within 1 km radius in urban area. Relationship between field strength and received signal power at the antenna connector is following [15]:

$$S(\text{dBm}) = 20 \log(f(\text{MHz})) + 77.2 - E\left(\frac{\text{dB}\mu\text{V}}{\text{m}}\right) + G(\text{dB}) \quad (1)$$

Where $S(\text{dBm})$ is signal power at the antenna connector in dBm, $f(\text{MHz})$ is used frequency in MHz and $E(\text{dB}\mu\text{V}/\text{m})$ is field strength in dB μ V/m, and $G(\text{dB})$ is antenna gain.

If antenna gain is taken into account, efficiency and directivity should be analyzed carefully. With mobile devices, we are interested in average gain, not peak gain, because device alignment is random. Another aspect is that in most of the cases signal is not arriving directly via line of sight channel, but rather via multipath route and peak gain or minimum gain are not interesting when average performance of sensing system is studied. Therefore antenna is assumed to have isotropic radiation pattern on average with measured antenna efficiency.

With measured prototype antenna, having antenna efficiency of -7.5 dB, simulated field strength corresponds -123 – (-83) dBm signal input power at the receiver. Taking measured detector sensitivity into account we end up 0.6 to 1 detection probability of Tallinn TV transmitter in Ruoholahti, Helsinki. Tallinn transmission on channel 45, adjacent to much stronger Espoo TV transmitter on channel 44 and 46, is masked and it cannot be detected. One must remember that transmissions from Tallinn are out of the reach for typical TV reception setups in Helsinki households.

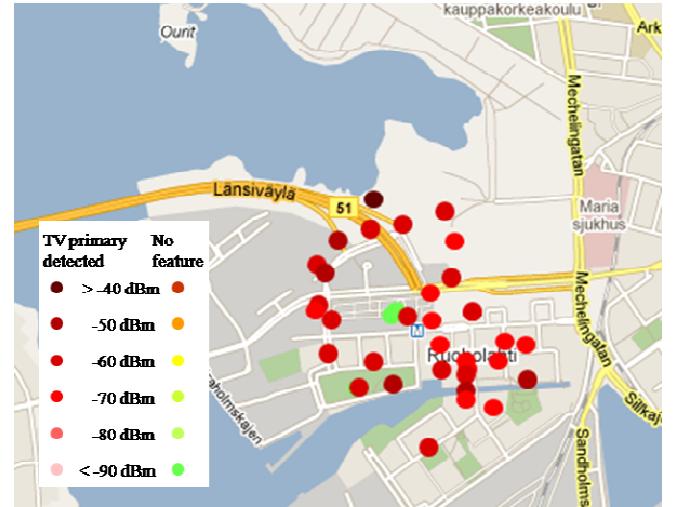

Fig. 1. Measurements results on UHF channel 44 (658 MHz) in Ruoholahti, Helsinki.

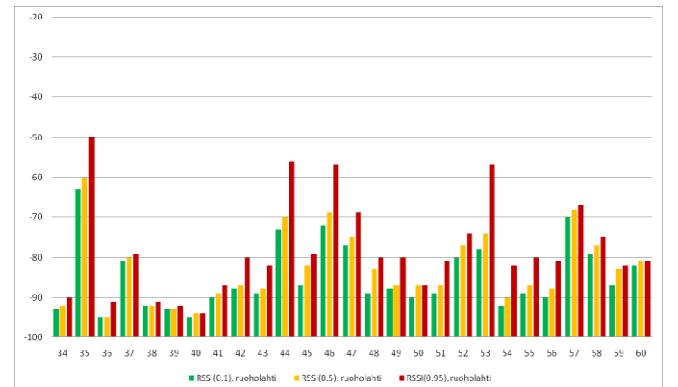

Fig. 2. Received signal strength (RSSI[dBm]) upper limit for 10%, 50% and 95% of measured samples in Ruoholahti.

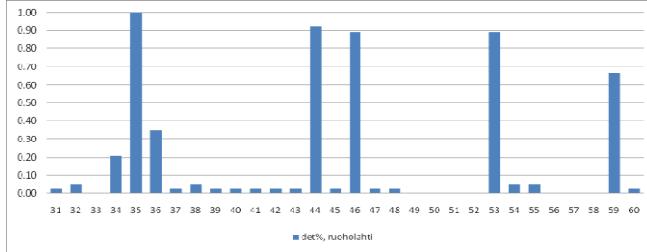

Fig. 3. Measured probability of DVB-T detection, n = 37 per UHF channel, average distance to Espoo transmitter 15 km and 78 km to Tallinn transmitter.

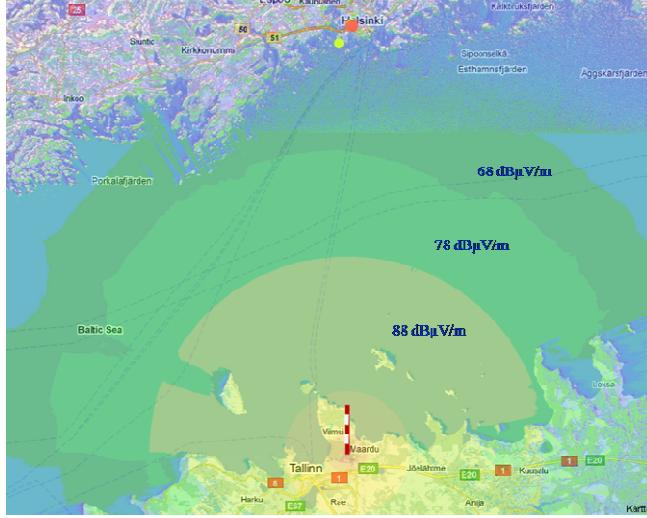

Fig. 4. Simulated field strengths on UHF channel 59 (778 MHz) from Tallinn TV tower, distance to Helsinki 77 km.

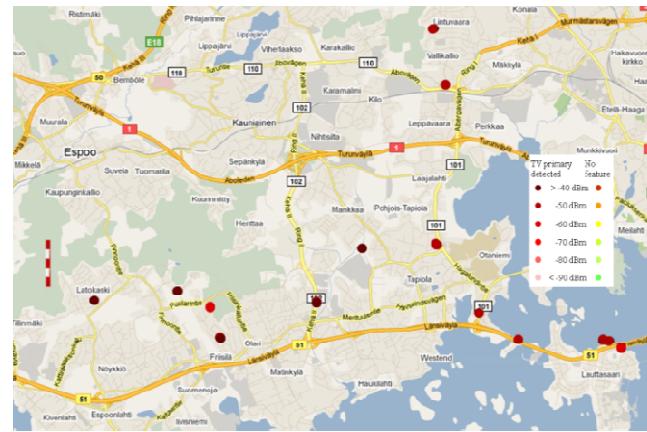

Fig. 5. Measurements results on UHF channel 44 (658 MHz) in Espoo, average distance to Espoo TV tower is 8 km.

Second set was measured outdoors in suburban Espoo and target was to evaluate performance of the spectrum sensor in the vicinity of strong TV transmitter. Measurements were done using two sensors one with internal antenna and another with external reference dipole. Measurement locations and results for occupied channel 44 (658 MHz) are shown in Fig. 5. Measured signal power on occupied channels was from -65 dBm up to -32 dBm, when using external reference dipole, as shown in Fig. 6. The RSSI[dBm] limits tell how many percent of measurement

samples have smaller RSSI value than presented. Basically this presents values of observed cumulative distribution function with 10%, 50% and 95% probabilities. TV signal strength is from 10 to 30 dB more than in the Helsinki measurement set. Main difference between results measured using internal and external antennas is that antenna efficiency of internal antenna is on average 7.5 dB lower than external reference dipole. Results using internal antenna are shown in Fig. 7. Difference in antenna efficiency means additional noise figure of 7.5 dB, which decreases sensitivity and increases linearity of receiver. In addition there is also device induced noise in internal antenna measurements. Performance difference is clearer with detection results shown in Fig. 8.

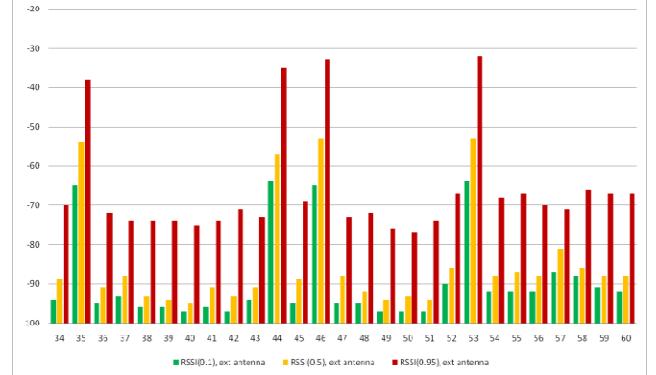

Fig. 6. Received signal strength (RSSI[dBm]) with external antenna, upper limit for 10%, 50% and 95% of measured samples in Espoo.

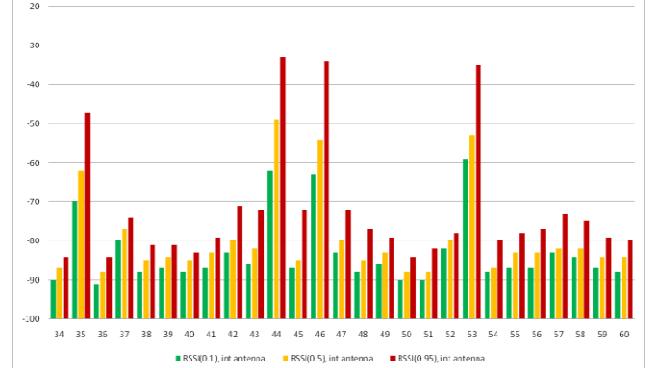

Fig. 7. Received signal strength (RSSI[dBm]) with internal antenna, upper limit for 10%, 50% and 95% of measured samples in Espoo.

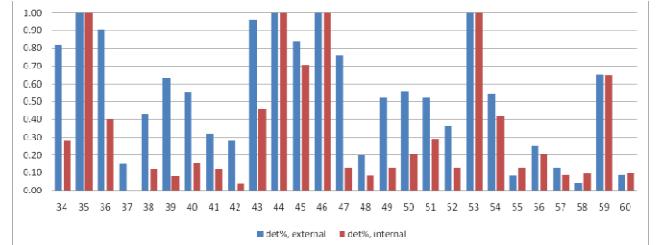

Fig. 8. Measured probability of DVB detection, number of detections is 26 per channel, average distance to Espoo transmitter 9km and 78 km to Tallinn transmitter.

IV. INTERMODULATION RESULT ANALYSIS

Memoryless weakly non-linear system model is widely used for modeling radio front-end nonlinear phenomena.

$$S_{\text{out}} = k_1 S_{\text{in}} + k_2 S_{\text{in}}^2 + k_3 S_{\text{in}}^3 \quad (2)$$

Equation (1) is based on truned Taylor series expansion. Almost always k_0 term i.e. DC offset is removed in receiver and it is not shown here. The first term with k_1 is the amplified version of S_{in} . The second and the third term will be called the 2nd order and 3rd order nonlinear terms, respectively. Those nonlinear terms generate different distortion products. Some of those distortion products fall into the band of interest. It is often assumed that UHF TV band selection filter can handle the second order term [10]. However, we show that this will not be the case with modulated signal, e.g. DVB. The effect of the 3rd order nonlinear terms cannot be ignored because their distortion products always fall inside the desired DTV spectrum.

In case of Espoo transmitter, DVB-T signals on channels 32, 35, 44, 46, and 53 we get input signal

$$S_{\text{in}} = \operatorname{Re} \left\{ \sqrt{2} \sum_{n=32,35,44,46,53} A_{tv,n} e^{i\omega_n} \right\} \quad (3)$$

Power level of intermodulation results can be calculated as follows

$$P_{IM3} = 3P_{in} - 2IIP_3 \quad (4)$$

$$P_{IM2} = 2P_{in} - IIP_2 \quad (5)$$

By using (2), (3), (4), wideband signal effect (Δ_{wideband}), and spectrum spreading with IM3 into account (66% on the channel and 17% to adjacent channels) [17], we get IM3 simulation results shown in Fig. 9. Calculated result is very similar than measured, that is shown in Fig. 6. IM2 result in (5) is used to derive IIP₂ requirement of spectrum sensor.

Spectrum sensor performance with single strong DVB transmission is verified by laboratory measurements. Signal is placed on channel 45 and detection probability is measured from channels 45, 46, 47, and 48. Results are shown in Fig. 10. Results measured on channel 45 shows the sensitivity of the prototype detector. DVB signal is detected from adjacent channel if its power is over -60 dBm and over -45 dBm signals can be seen even more than 4 channels away. Baseband filter bandwidth is set to 5 MHz, the same than used in field measurements. In addition, signal is oversampled by a factor of 4 and digital filtering attenuates adjacent channel signal down to quantization noise before the detector, thereby excluding aliasing effects from the neighboring channels. It is quite obvious that a seen phenomenon comes from second order intermodulation of the sensor front-end. Most likely from self-mixing of modulated signal.

In order to guarantee enough capacity for sensing devices, IIP₃ and IIP₂ requirement for spectrum sensor

should be specified. To avoid false detections due to IM products, IIP₃ and IIP₂ requirements should be set so that resulting IM products power will be under constant false alarm threshold. In case of used cyclostationary feature detector, this level is -124 dBm. In our field measurements 95% of detected signal levels were under -30 dBm, corresponding requirements for IIP₃ of 17 dBm, and IIP₂ of 64 dBm with external dipole antenna. With built-in UHF antenna, same requirements are 5.7 dBm IIP₃ and 49 dBm IIP₂. One should remember that the prototype meet FCC sensitivity requirements only in upper part of UHF TV band, because antenna efficiency is very poor in lower part. How cyclostationary features will behave in non-linear spectrum sensor front-ends should be investigated more and this approach could provide interesting methods to avoid problems with IM products.

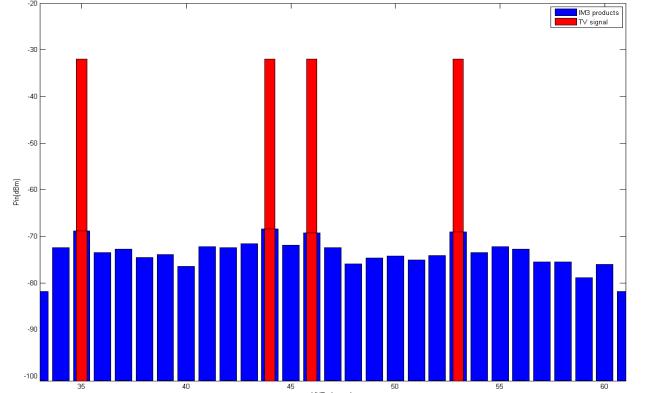

Fig. 9. Calculated power level of IM3 products, IIP₃ = -10, in case of five -32 dBm DVB-T signals on UHF channels 32, 35, 44, 46, and 53.

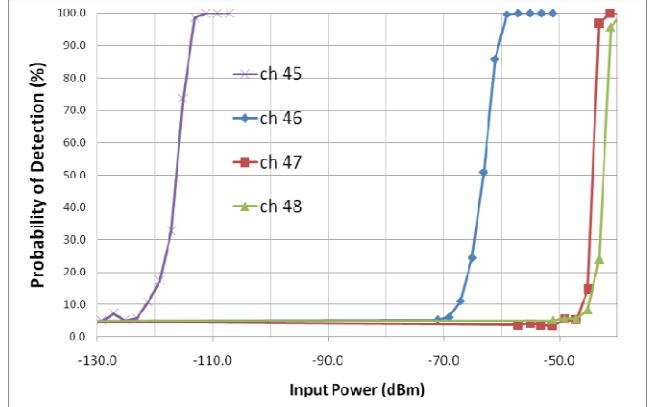

Fig. 10. Adjacent channel measurement results: DVB signal transmitted on channels 45, measured detection probabilities from channels 45, 46, 47, and 48.

V. CONCLUSIONS

We have shown by field measurements that single device single snapshot detection is too unreliable due antenna gain minima, interference, and fading to protect primary users. Just tightening of sensitivity requirement does not help, because IM products cause desensitization, masking, and false alarms, thus reducing available capacity for secondary

users [18]. Methods like geo location databases and using collaborative sensing are developed to solve these problems. Collaborative sensing averages antenna gain and radio propagation problem. However presented trade-offs between sensitivity in sensor linearity requirement and sensitivity has to be taken into account in algorithm development. Collaborative use of network of large amount of cheap spectrum sensors embedded to e.g. mobile phones is interesting and practical approach to solve spectrum sensing problem. Estimation of multi-dimensional spectrum utilization field, using compressive sensing techniques in collaborative spectrum sensing network is interesting approach for enabling truly cognitive radios.
